## Abstract

*Salmonella* Typhimurium (*S. Typhimurium*) is an enteric bacterium capable of invading a wide range of hosts, including rodents and humans. It targets different host cell types showing different intracellular lifestyles. *S. Typhimurium* colonizes different intracellular niches and is able to either actively divide at various rates or remain dormant to persist. A comprehensive tool to determine these distinct *S. Typhimurium* lifestyles remains lacking. Here we developed a novel fluorescent reporter, *Salmonella* Intracellular Analyzer (SINA), compatible for fluorescence microscopy and flow cytometry in single-bacterium level quantification. This identified a *S. Typhimurium* subpopulation in infected epithelial cells that exhibits a unique phenotype in comparison to the previously documented vacuolar or cytosolic *S. Typhimurium*. This subpopulation entered a dormant state in a vesicular compartment distinct from the conventional *Salmonella*-containing vacuoles (SCV) as well as the previously reported niche of dormant *S. Typhimurium* in macrophages. The dormant *S. Typhimurium* inside enterocytes were viable and expressed *Salmonella* Pathogenicity Island 2 (SPI-2) virulence factors at later time points. We found that the formation of these dormant *S. Typhimurium* is not triggered by the loss of SPI-2 effector secretion but it is regulated by (p)ppGpp-mediated stringent response through RelA and SpoT. We predict that intraepithelial dormant *S. Typhimurium* represents an important pathogen niche and provides an alternative strategy for *S. Typhimurium* pathogenicity and its persistence.

## Author summary

*Salmonella* Typhimurium is a clinically relevant bacterial pathogen that causes Salmonellosis. It can actively or passively invade various host cell types and reside in a *Salmonella*-containing vacuole (SCV) within host cells. The SCV can be remodeled into a replicative niche with the aid of *Salmonella* Type III Secretion System 2 (T3SS2) effectors or else, the SCV is ruptured for the access of the nutrient-rich host cytosol. Depending on the infected host cell type, *S. Typhimurium* undertake different lifestyles that are distinct by their subcellular localization, replication rate and metabolic rate. We present here a novel

fluorescent reporter system that rapidly detects *S. Typhimurium* lifestyles using fluorescence microscopy and flow cytometry. We identified a dormant *S. Typhimurium* population within enterocyte that displays capacities in host cell persistence, dormancy exit and antibiotic tolerance. We deciphered the (p)ppGpp stringent response pathway that suppresses *S. Typhimurium* dormancy in enterocytes while promoting dormancy in macrophages, pinpointing a divergent physiological consequence regulated by the same set of *S. Typhimurium* molecular mediators. Altogether, our work demonstrated the potential of fluorescent reporters in facile bacterial characterization, and revealed a dormant *S. Typhimurium* population in human enterocytes that are phenotypically distinct from that observed in macrophages and fibroblasts.

## Introduction

*Salmonella enterica* serovar Typhimurium (*S. Typhimurium*) is an enteric bacterium that closely associates with global food-borne illnesses. The prevalence of *S. Typhimurium* has placed a severe burden on the global food and healthcare industry, leading to millions of cases, hundreds of casualties and costing billions of dollars per annum [1,2]. *S. Typhimurium* resides in different natural reservoirs and is transmitted to humans through contaminated food.

Upon arrival in the human intestine after ingestion, a portion of the luminal *S. Typhimurium* expresses the Type III Secretion System 1 (T3SS1) encoded within *Salmonella* Pathogenicity Island 1 (SPI-1) and its cognate effectors to induce its active entry into non-phagocytic epithelial cells. *S. Typhimurium* also targets other cell types, such as fibroblasts and macrophages. During these events, it induces local tissue injuries and eventually breaches the intestinal barrier to reach the lamina propria and tissue-resident immune cells. Then, *S. Typhimurium* is carried by macrophages to mesenteric lymph nodes and eventually to the liver and spleen for persistent infection [3].

Within enterocytes *S. Typhimurium* are encapsulated in an endocytic compartment coined *Salmonella*-containing vacuole (SCV) that matures by acidification within the first hours of internalization [4]. The reducing pH and changing osmolarity of the SCV induce the shut-down of T3SS1 and expression of a second T3SS, T3SS2, from *Salmonella* Pathogenicity Island 2 (SPI-2) [5,6]. The T3SS2 effectors remodel the SCV into a viable niche for *S. Typhimurium* replication [5,6]. Default maturation of the SCV is marked by the sequential acquisition and removal of endocytic trafficking markers, such as the small GTPases RAB5 and RAB7 as well as Lysosome-associated membrane glycoprotein 1 (LAMP1) [7]. During these events, the SCV dynamically interacts with surrounding macropinosomes, which controls SCV stability [8,9]. Consequently, *S. Typhimurium* can reside either in a remodeled SCV or disrupt the SCV to access the host cytosol. Overall, *S. Typhimurium* exhibits distinct replication rates and specific metabolic profiles within the different intracellular niches adapting to nutrient availability and the specific microenvironments [8–10].

Differential lifestyles are also known for *S. Typhimurium* infecting other cell types. In fibroblasts, the SCV associates with the autophagy machinery that either clears the infection or allows *S. Typhimurium* to putatively persist in the cell [11,12]. In macrophages, *S. Typhimurium* expresses the T3SS2 to remodel the SCV immediately after bacterial entry, or the pathogen adopts a dormant behavior mediated by toxin-antitoxin (TA) system [13,14].

Antibiotic persistence and relapse of *S. Typhimurium* infection due to the failure of bacterial eradication through antibiotic treatment has been tied to *S. Typhimurium* dormancy, which is distinct from bacterial persistence that refers to incompletely cleared infections by the

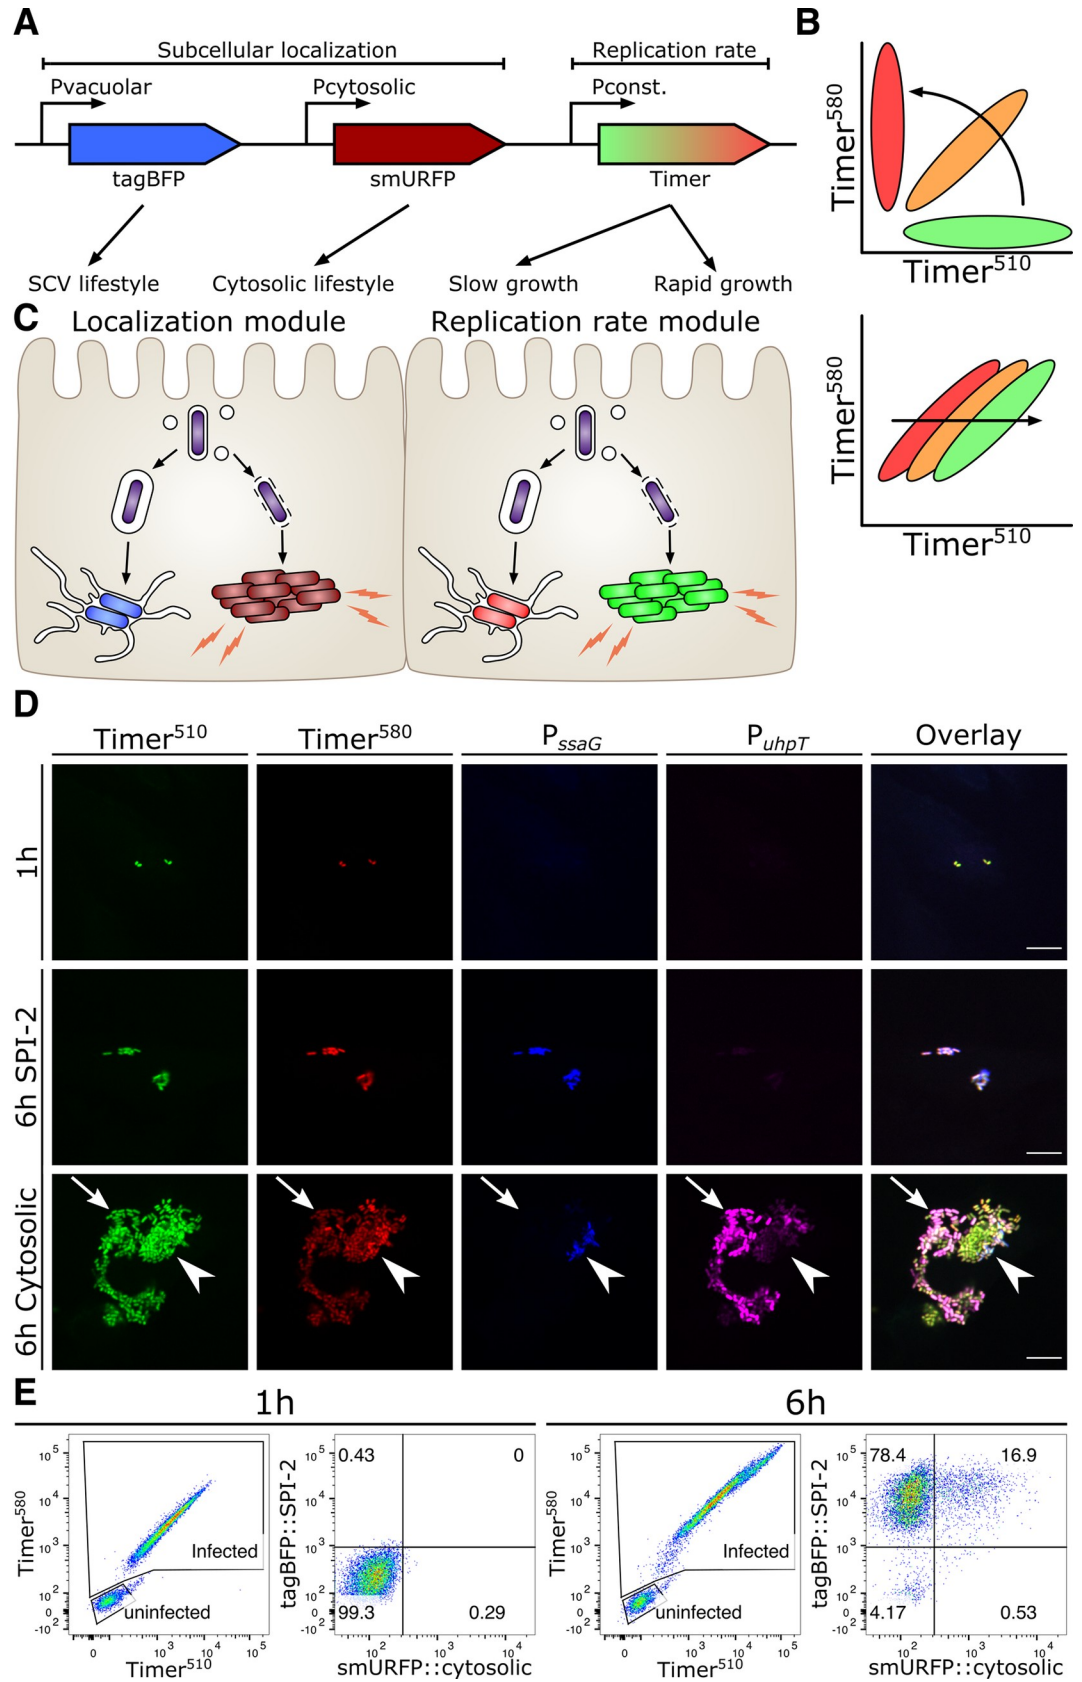

immune system. Numerous antibiotics target major active machineries, including DNA replication, transcription and translation of extracellular bacteria, therefore dormant intracellular pathogens appear to be less or not susceptible to such treatments [15]. *S. Typhimurium* dormancy and antibiotics persistence have been reported in macrophages to be regulated by the Guanosine pentaphosphate (ppGpp) stringent response pathway. The two (p)ppGpp synthases RelA and SpoT control the bacterial (p)ppGpp level, which regulates the activity of the ATP-dependent protease Lon to degrade the antitoxin and release the toxin TacT for arresting protein translation [14,16]. The arrest of translation by TacT leads to a halt of bacterial growth giving rise to the insensitivity and tolerance towards antibiotics [16]. Despite reports of *S. Typhimurium* antibiotics persistence in the epithelium and lamina propria of the mouse intestine, it is not clear whether this involves dormant bacteria [17].

With our *Salmonella* INtracellular Analyzer (SINA) system, we precisely depicted the intracellular bacterial lifestyles at the single bacterium level, identifying a novel *S. Typhimurium* population within enterocytes that is dormant. Dormant persisters within enterocytes are localized in a unique vacuolar compartment different from the one described in macrophages. We found that T3SS2 effector secretion and the Lon protease are dispensable for this new *S. Typhimurium* population, while the bifunctional enzyme SpoT and monofunctional enzyme RelA negatively regulate *S. Typhimurium* dormancy in epithelial cells.

## Results

### Development of a multiplex fluorescent reporter series, the *Salmonella* INtracellular Analyzer (SINA) to distinguish different intracellular *S. Typhimurium* lifestyles

The distinct intracellular lifestyles of *S. Typhimurium* upon invasion of epithelial cells have been described either with regard to the specific pathogen localization or with regard to the bacterial growth dynamics. To date, fluorescent reporters are available to identify *S. Typhimurium* within vacuolar and cytosolic localizations; while the others measure the replication rate of the pathogen [18–20]. However, these localization and replication-rate reporters have not been coupled, as it has been generally assumed that the bacterial localization determines its replication rate. This notion has been challenged by different reports, for example on the different growth rates of *S. Typhimurium* within the cytosol depending on the targeting by autophagy [21–25]. A combined reporter system would enable a comprehensive elucidation of the intracellular lifestyle of a given intracellular pathogen. Therefore, we developed a novel fluorescent reporter series, the *Salmonella* INtracellular Analyzer (SINA). Our SINA1.1 reporter is composed of two separated modules to indicate the bacterial localization and replication rate. The localization module consists of two transcription reporters driven by localization-specific promoters, while the replication rate module carries a constitutively expressed fluorescent timer (Figs 1A and S1). At the molecular level, the localization module is composed of vacuolar (Vac) and cytosolic (Cyt) submodules, which utilize two characterized promoters,  $P_{ssaG}$  and  $P_{uhpT}$  to drive the expression of tagBFP and smURFP, respectively [18,19]. We confirmed the functionality of the fluorescent  $P_{ssaG}$  and  $P_{uhpT}$  reporters for our experimental setup during *S. Typhimurium* invasion of epithelial cells using a digitonin assay assayed by flow cytometry (S2 and S3 Figs). The replication rate module encodes Timer<sup>bac</sup>, a DsRed mutant (S197T), which has been previously employed to differentiate *S. Typhimurium* subpopulations by their replication rates [20]. The emission spectrum of Timer<sup>bac</sup> shifts from green to red as it matures, which reflects the bacterial metabolic activity (change in slope, Fig 1B top) as well as the replication rate (unvarying slope, varying green:red ratio, Fig 1B bottom) [26]. When Timer<sup>bac</sup> is constitutively expressed, a metabolically active *S. Typhimurium* bacterium emits both green

**Fig 1. SINA enables precise determination of the different *Salmonella* intracellular lifestyles in human epithelial cells.**

(A) Schematic diagram of the construction of subcellular localization and replication rate modules of SINA1.1. The subcellular localization module is composed of the vacuolar submodule ( $P_{ssaG}$ -tagBFP) and cytosolic submodule ( $P_{uhpT}$ -smURFP), while the replication rate module is composed of a constitutively expressed  $\text{Timer}^{\text{bac}}$  ( $P_{ybaJ}$ - $\text{Timer}^{\text{bac}}$ ) (B) (Top) Schematic diagram of the emission spectrum shifts of *S. Typhimurium* harboring  $\text{Timer}^{\text{bac}}$  as  $\text{Timer}^{\text{bac}}$  matures, where emission shifts from green to red (Bottom) Green:Red ratio increases with elevating *S. Typhimurium* replication rates. As *S. Typhimurium* divides, both  $\text{Timer}^{510}$  and  $\text{Timer}^{580}$  fluorophores are diluted. With a higher production rate of  $\text{Timer}^{510}$  than  $\text{Timer}^{580}$ , fast dividing *S. Typhimurium* exhibits a higher Green:Red ratio. (C) Expected output by SINA as *S. Typhimurium* dwells in distinct subcellular localizations. Vacuolar *S. Typhimurium* are of lower replication rate (i.e. lower Green:Red ratio) and are expected to emit blue fluorescence; cytosolic *S. Typhimurium* are of higher replication rate (i.e. higher Green:Red ratio) and are expected to emit far red fluorescence (D) HeLa cells infected by *S. Typhimurium* harboring SINA1.1. Output of SINA from intracellular *S. Typhimurium* was detected by fluorescence microscopy at 1 h pi, vacuolar (arrowhead) and cytosolic (arrow) *S. Typhimurium* at 6 h pi. (3 independent experiments). Scale bars are 10  $\mu\text{m}$ . (E) HeLa cells infected by *S. Typhimurium* harboring SINA1.1. Output of SINA from intracellular *S. Typhimurium* at 1 h and 6 h pi was detected by flow cytometry (3 independent experiments).

<https://doi.org/10.1371/journal.ppat.1009550.g001>

and red signals resulting from immature green and mature red fluorophores. In case such a bacterium experiences a metabolic halt, it eventually emits only red signals, due to the maturation of the existing green fluorophores in concert with ceased *de novo* synthesis of the green fluorophores. With SINA, we are able to simultaneously collect information on these replication rate changes of *S. Typhimurium* and its localization at single bacterium resolution, which enables a comprehensive and quantitative reflection of *S. Typhimurium* physiology inside an infected host.

To validate the functionality of our SINA system during *S. Typhimurium* invasion of epithelial cells, we employed fluorescence microscopy and flow cytometry analysis (Fig 1C). With fluorescence microscopy, we observed intracellular *S. Typhimurium* simultaneously emitting both green and red signals ( $\text{Timer}^{\text{bac}}$ ), but not Vac ( $P_{ssaG}$ -tagBFP) and Cyt ( $P_{uhpT}$ -smURFP) signals at 1 hour post-infection (pi) (Fig 1D). As these bacteria committed to vacuolar or cytosolic lifestyles at 6 hours pi, we observed that *S. Typhimurium* in cells with <10 bacteria emitted Vac signal during this time course. On the other hand, we observed a mixed population of *S. Typhimurium* in cells with >10 bacteria, where clusters of  $\text{Cyt}^+$  *S. Typhimurium* of low  $\text{Timer}^{\text{bac}}$  signals (arrow) and individual  $\text{Vac}^+$  *S. Typhimurium* (arrowhead) were detected. In the cells containing mixed *S. Typhimurium* populations, bacteria were either  $\text{Vac}^+$  or  $\text{Cyt}^+$  but not double positive, showing the presence of two populations with distinct discernible lifestyles (Fig 1D). We were also able to track the onset of bacterial division and signal output from SINA by time-lapse microscopy (S1–S3 Movies, S4B and S4C Fig).

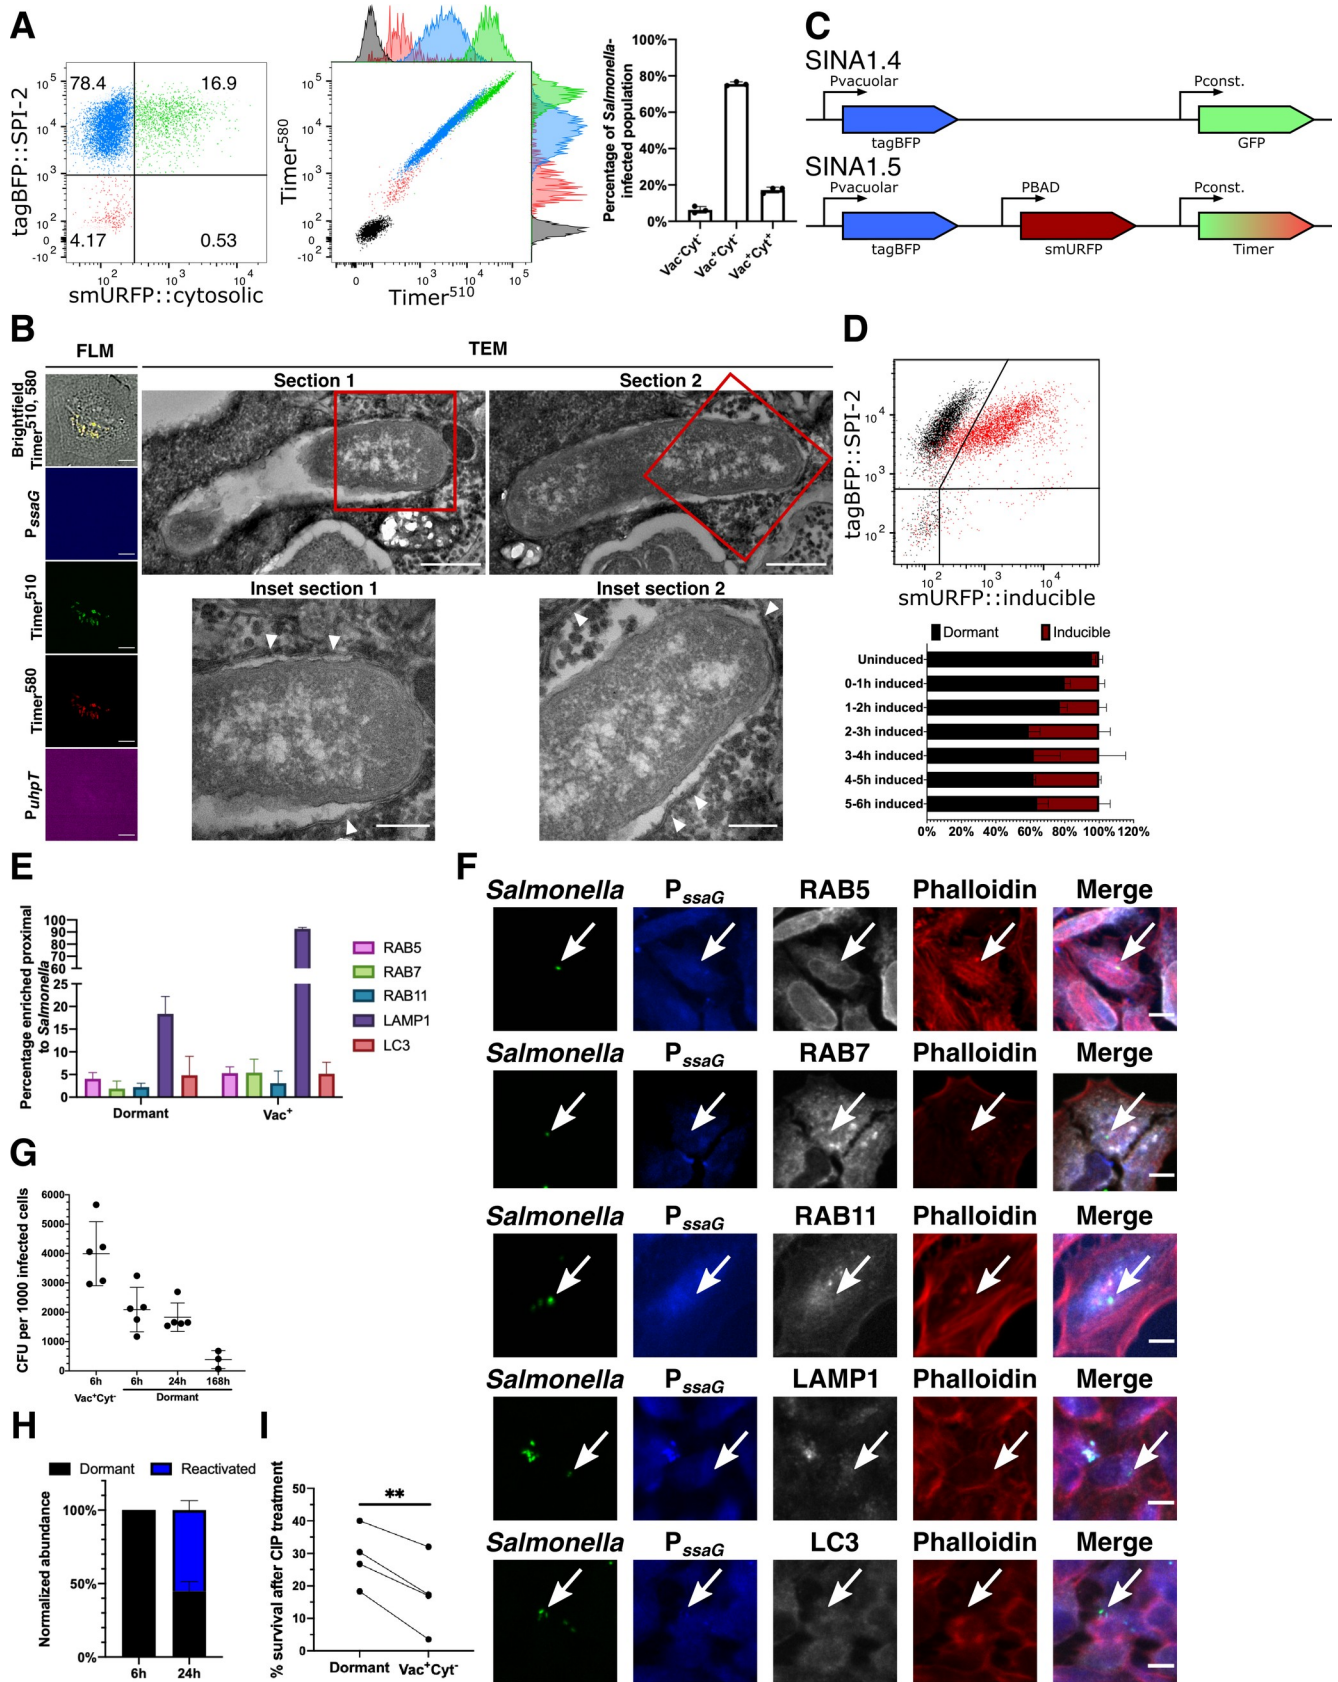

We took advantage of the properties of our multiplex SINA reporter and devised a gating strategy to quantitatively analyze the bacterial lifestyles in single *S. Typhimurium*-infected cells using flow cytometry (S2 Fig). In brief, we first defined the infected cells by the size of the analyzed events (under SSC-A vs FSC-A plot), followed by the positive signals in the  $\text{Timer}^{580}$  vs  $\text{Timer}^{510}$  plot (i.e. cells harboring *S. Typhimurium*). We then further classified the *S. Typhimurium*-infected cells into four sub-types according to the signals of the localization module (tagBFP::SPI-2 vs smURFP::cytosolic plot), corresponding to cells with either vacuolar bacteria ( $\text{Vac}^+\text{Cyt}^-$ ) or cytosolic bacteria ( $\text{Vac}^-\text{Cyt}^+$ ) or cells with both vacuolar and cytosolic populations ( $\text{Vac}^+\text{Cyt}^+$ ) or cells harboring *S. Typhimurium* that express only basal levels of the Vac and Cyt signals (S2 Fig). We observed that intracellular *S. Typhimurium* behaved as a population with a homogenous replication rate and basal expression levels of Vac and Cyt at 1 hour pi (Fig 1E). At 6 hours pi, this homogenous population segregated into  $\text{Vac}^+$  and  $\text{Cyt}^+$  subpopulations, with a  $\text{Cyt}^+$  distribution similar to that reported in the literature (10–20% cytosolic) (Fig 1E) [21]. The gradual separation of these subpopulations could be detected with SINA1.1 throughout the course of infection (S4A Fig). As we backgated the infected cells, we observed cells harboring only vacuolar *S. Typhimurium* ( $\text{Vac}^+\text{Cyt}^-$ ) and cells with both vacuolar and

cytosolic bacteria ( $\text{Vac}^+\text{Cyt}^+$ ), each forming a distinct population of different Green:Red ratio on the plot of  $\text{Timer}^{510}$  against  $\text{Timer}^{580}$  (S5A Fig). Together, this demonstrated that our novel SINA1.1 reporter is capable of simultaneously and quantitatively distinguishing the *S. Typhimurium* lifestyles by their subcellular localization and replication rate at both single infected cell and single bacterium level using flow cytometry and fluorescence microscopy. The combination of the SINA reporter with flow cytometry fosters higher throughput analysis of *S. Typhimurium* lifestyles in infected cells as compared to microscopy, extending the possibility for rapid screening.

### A novel dormant *S. Typhimurium* subpopulation in human epithelial cell

With the SINA1.1 reporter, we used the SPI-2 expression module to distinguish vacuolar *S. Typhimurium* from cytosolic bacteria. In the plot of the localization module, we identified an easily discernable population (~5–10%) of infected epithelial cells harboring  $\text{Vac}^-\text{Cyt}^-$  *S. Typhimurium* detectable as early as 2 hours pi, which became apparent at 6 hours pi (Figs 2A and S6). We backgated the  $\text{Vac}^-\text{Cyt}^-$  population, and we extracted physical parameters from the  $\text{Timer}^{\text{bac}}$  plot. This revealed that the  $\text{Vac}^-\text{Cyt}^-$  *S. Typhimurium* exhibit a similar replication rate (S5A Fig) but a reduced metabolic activity (S5B Fig) compared to  $\text{Vac}^+\text{Cyt}^-$  *S. Typhimurium* as depicted by the green:red ratio and slope of  $\text{Timer}^{\text{bac}}$  plot, respectively. The capacities of  $\text{Timer}^{\text{bac}}$  in the measurement of the bacterial replication rate and metabolism have been well-elaborated in previous applications [20,27]. This  $\text{Vac}^-\text{Cyt}^-$  *S. Typhimurium* population was also visualized using live microscopy to confirm their presence using different detection approaches (S3 Movie). This was intriguing as metabolically inactive *S. Typhimurium* have not been reported in enterocytes so far. We thus infected polarized intestinal epithelial Caco-2 monolayers, and confirmed the presence of the  $\text{Vac}^-\text{Cyt}^-$  subpopulation with a shifted metabolic profile in a cellular model system for intestinal infections (S7 Fig). We also performed control infections in 3T3 (fibroblast model) and differentiated THP-1 cells (macrophage model) to test the sensitivity of SINA1.1 in these relevant cell types. As within epithelial cells, we also observed distinct *S. Typhimurium* populations in the macrophage and fibroblast models as described before (S8 and S9 Figs). To determine the intracellular localization of  $\text{Vac}^-\text{Cyt}^-$  *S. Typhimurium*, we further performed correlative light and electron microscopy (CLEM) by serial section transmission electron microscopy (TEM), and a digitonin assay demonstrating that this subpopulation is localized in a host vesicular compartment (Figs 2B, S4A–S4F and S10) [21]. Together, these results showed the presence of a novel intracellular *S. Typhimurium* population within epithelial cells that exhibits a lowered metabolic rate and resides in a host vesicular compartment, implicating a putative dormant phenotypic variant.

Intracellular *S. Typhimurium* encounters a number of stresses upon uptake into host cells, including oxidative, pH and osmotic stress, which serve as key signals to trigger transcription reprogramming for the adaptation of an intra-host environment [28]. As the intracellular microenvironment and *S. Typhimurium* dormancy has been studied in some detail in macrophages, we decided to focus our comparison on this cell type in relation to the newly identified *S. Typhimurium* subpopulation in epithelial cells. During macrophage infections the SCV microenvironment drives a portion of *S. Typhimurium* into a dormant state that contributes to the elevation of antimicrobial persistence and polarization of infected macrophage [14,29]. We asked whether  $\text{Vac}^-\text{Cyt}^-$  *S. Typhimurium* shares similar physiologies with dormant *S. Typhimurium* inside macrophages, hence we determined the metabolic state of the  $\text{Vac}^-\text{Cyt}^-$  population. By replacing the cytosolic submodule of SINA1.1 with an arabinose inducible cassette to generate SINA1.5, we measured *S. Typhimurium*'s capacity to respond to arabinose treatment. This modification enabled us to directly monitor the metabolic activity of *S.*

**Fig 2. *S. Typhimurium* displays a novel inactive intracellular lifestyle in epithelial cells.** (A) (Left and Middle) Timer<sup>bac</sup> profile and distribution of single cells with no infection (black), infected cells with inactive bacteria (Vac<sup>-</sup>Cyt<sup>-</sup>) (red), infected cells with only vacuolar bacteria (Vac<sup>+</sup>Cyt<sup>-</sup>) (blue) and infected cells with both vacuolar and cytosolic populations (Vac<sup>+</sup>Cyt<sup>+</sup>) (green) at 6 h pi. <https://doi.org/10.1371/journal.ppat.1009550.g002>

*Typhimurium* during the infection process (Fig 2C). The response of intracellular bacteria towards extracellular arabinose induction has been reported previously to characterize the metabolic state of macrophage-borne dormant *S. Typhimurium* [13]. With SINA1.5, we observed that approximately half of the Vac<sup>-</sup> *S. Typhimurium* did not respond to arabinose induction at designated time intervals (Fig 2D). As the Vac<sup>-</sup>Cyt<sup>-</sup> bacterial niche may show limited arabinose accessibility, we corroborated our observations monitoring the reduced metabolism of this bacterial population via the signals of the Timer<sup>bac</sup> reporter (S5B Fig). These data allowed us to propose that the Vac<sup>-</sup>Cyt<sup>-</sup> *S. Typhimurium* adopts a dormant state (coined as dormant *S. Typhimurium* hereafter) upon their internalization into epithelial cells.

### Dormant *S. Typhimurium* resides in a unique vesicular compartment

We set out to determine whether the dormant *S. Typhimurium* localization is distinct from conventional SCVs. To determine this by immunofluorescence staining, we simplified SINA1.1 to SINA1.4 to free the red and far-red channels for indirect immunofluorescence staining of selected endocytic markers (Fig 2C). LAMP1 labels host lysosomes as well as the matured SCV, which is also present on the SCV of dormant *S. Typhimurium* in macrophages [7,13]. By fluorescence microscopy, we only observed minor recruitment of LAMP1 to the proximity of dormant *S. Typhimurium* within epithelial cells, in contrast to the high LAMP1 incidence proximal to Vac<sup>+</sup> *S. Typhimurium* (Fig 2E and 2F). We also determined if dormant *S. Typhimurium* is localized in a SCV experiencing a halt in SCV biogenesis, therefore we tested a number of known early SCV markers (namely RAB5, RAB7 and RAB11). We did not observe the recruitment of any of these early SCV markers to the dormant *S. Typhimurium* (Fig 2E and 2F). This was intriguing as our previous ultrastructural and digitonin investigations clearly documented the dormant *S. Typhimurium* bacteria within a membrane-bound compartment. We also addressed if the dormant population is targeted by host autophagy, analyzing the localization of the autophagy marker LC3. We did not detect any localization of LC3 proximal to the majority of the dormant *S. Typhimurium* (Fig 2E and 2F). Therefore, we conclude that dormant *S. Typhimurium* are localized within a unique membrane-bound compartment distinct from the conventional SCV and that of dormant *S. Typhimurium* in macrophages, suggesting such dormancy formation is heavily governed by endocytic trafficking [13,30]. This compartment requires further characterization in future studies.

## Dormant *S. Typhimurium* are viable, cultivable, resume metabolism and express virulence genes in host cells

Endocytic vesicles are either recycled or undergo fusion with the lysosomes for degradation. The same fate also applies to vacuolar *S. Typhimurium*, where SPI-2 deficient strains have a reduced survival capacity compared to SPI-2 competent strains [31]. We collected the infected cells harboring dormant *S. Typhimurium* by cell sorting at >90% purity and plated them for colony forming unit (CFU) measurement, a classical approach to determine the viability of the intracellular *S. Typhimurium*. We observed that dormant *S. Typhimurium* are viable and cultivable (Fig 2G), contrasting to the viable but not cultivable nature of dormant *S. Typhimurium* in murine macrophages [13,14]. To determine the fate of the dormant *S. Typhimurium*, we enriched and plated the viable infected cells harboring dormant *S. Typhimurium*, and monitored the bacterial behavior at 24 hours pi (S11 Fig). We observed that 50% of the dormant *S. Typhimurium* in infected cells collected at 6 hours pi became metabolically active and expressed SPI-2 at 24 hours pi, as demonstrated by the population shift in the Timer<sup>bac</sup> plot, and becoming Vac<sup>+</sup> (Fig 2H). To determine if the dormant *S. Typhimurium* persists in the host, we further enriched infected cells harboring dormant *S. Typhimurium* and monitored the presence and the viability of dormant *S. Typhimurium* at 7 days pi. The dormant *S. Typhimurium* were found to persist in cells and remained viable and cultivable over the whole period of 7 days (Fig 2G, “168h”). To further address whether the dormant intracellular *S. Typhimurium* phenotype confers a reduced sensitivity towards antibiotics, we supplemented ciprofloxacin (CIP) to the infected cell at 3 hours pi and determined the viability of dormant *S. Typhimurium* by CFU. We selected the *in cellulo* CIP supplementation to avoid artificial perturbations on the *S. Typhimurium* dormant status. Also, *in cellulo* treatment addresses the killing efficiency of dormant *S. Typhimurium* within the SCV, where subcellular distribution of this drug has been demonstrated to influence the bactericidal efficacy [32]. We observed a higher survival rate of dormant *S. Typhimurium* as compared to vacuolar *S. Typhimurium* (Fig 2I), similar to the observations made in the murine intestine [17]. These results demonstrated that dormant *S. Typhimurium* are viable, exhibit a delayed expression of SPI-2, persist in the epithelial host cells for up to 7 days and are less susceptible to antibiotics. Such unique metabolic and virulence reprogramming could serve as a strategic step for intestine-borne *S. Typhimurium* to prolong gut inflammation for community benefits and reservoir for relapse [33].

## *S. Typhimurium* dormancy is not a result of the loss of T3SS2 effector secretion

We then studied whether the lack of T3SS2 effector secretion drives *S. Typhimurium* dormancy in epithelial cells. Using our SINA1.1 reporter in the *S. Typhimurium* SPI-2 secretion deficient mutant  $\Delta$ *ssaV* [34], we observed no significant difference in the proportion of Vac<sup>-</sup> Cyt<sup>-</sup> *S. Typhimurium* between wild type and the  $\Delta$ *ssaV* mutant (Fig 3A). Altogether, the formation of dormant *S. Typhimurium* is not a consequence caused by the lack of T3SS2 effector secretion during the infection of epithelial cells.

## *S. Typhimurium* dormancy is regulated by (p)ppGpp biogenesis

Class II toxin-antitoxin (TA) systems regulate the dormancy formation of non-pathogenic *E. coli* in laboratory conditions [35]. TA systems are comprised of a toxin and an antitoxin that counter-balances the toxin to regulate bacterial physiology, including growth arrest. A major TA system involves the stringent response mediated by the monofunctional (p)ppGpp

**Fig 3. *S. Typhimurium* dormancy is negatively regulated by SpoT.** (A) HeLa cells were infected with SINA1.1-harboring *S. Typhimurium*, the abundance of Vac<sup>-</sup>Cyt<sup>+</sup> population in wild type and SPI-2 mutant  $\Delta$ ssaV infected cells were quantified with flow cytometry at 6 h pi. (n = 3) (B) Schematic diagram for the construction of SINA derivative, SINA1.9, yielded from the introduction of an arabinose-inducible *hila* expression cassette into SINA1.1. SINA1.9 was used to rescue the reduced invasiveness of  $\Delta$ dksA,  $\Delta$ relA and  $\Delta$ relAspoT mutant strains. (C) HeLa cells were infected with SINA1.1 or SINA1.9-harboring *S. Typhimurium*, the abundance of Vac<sup>-</sup>Cyt<sup>+</sup> population in (p)ppGpp biogenesis and regulon mutants,  $\Delta$ lon,  $\Delta$ dksA,  $\Delta$ relA and  $\Delta$ relAspoT were quantified by flow cytometry at 6 h pi (n = 3) (D) Distribution of Vac<sup>-</sup>Cyt<sup>+</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> populations in *hila*-expressing wild type (Left) and  $\Delta$ relAspoT mutant (Middle) infected HeLa cells at 6 h pi quantified by flow cytometry. (3 independent experiments) At least a total of 1000 events of infected cells were analyzed by flow cytometry in triplicate experiments. Statistics were performed using unpaired t test. ns: not significant ( $P > 0.05$ ), \*\* $P < 0.01$ , \*\*\*\* $P < 0.0001$ .

<https://doi.org/10.1371/journal.ppat.1009550.g003>

synthases RelA and bifunctional (p)ppGpp synthases SpoT, after which (p)ppGpp binds to DksA to mediate transcription reprogramming for bacterial adaptation. The surge in (p)ppGpp levels also activates the ATP-dependent Lon protease to degrade Type II antitoxins to release the free toxins [36–38]. In recent reports, stringent response has been associated with slow growing *S. Typhimurium* populations, and TA systems are implicated in *S. Typhimurium* dormancy in macrophages [14,16]. Therefore, we assessed the links between the stringent response and *S. Typhimurium* dormancy in epithelial cells, studying the mutant strains (i)  $\Delta$ relA ((p)ppGpp synthase), (ii)  $\Delta$ relA $\Delta$ spoT ((p)ppGpp synthases), (iii)  $\Delta$ dksA ((p)ppGpp-binding transcription regulator) and (iv)  $\Delta$ lon (protease targeting antitoxin). With the  $\Delta$ lon mutant, we did not observe any difference in the level of dormant *S. Typhimurium* population in infected cells (~5–10%), suggesting that Lon protease is dispensable for *S. Typhimurium* dormancy in epithelial cells (Fig 3C). As  $\Delta$ relAspoT and  $\Delta$ dksA were reported to suffer reduced invasiveness in epithelial cells due to the reduced SPI-1 expression, we thus constructed SINA1.9 (Fig 3B), a derivative of SINA1.1 with an additional cassette for an inducible expression of *hila* to compensate the reduced invasiveness of the mutants (S12 Fig) following a

previously published experimental strategy [39]. With the SINA1.9-complemented mutant strains, we obtained rescued invasiveness as compared to wild type *S. Typhimurium*. This allowed us to address the requirement of (p)ppGpp biogenesis and (p)ppGpp-regulated transcription for *S. Typhimurium* persistence. A significant increase in the Vac<sup>-</sup>Cyt<sup>-</sup> population was observed in  $\Delta relAspoT$ , whereas the increment was less pronounced in the  $\Delta relA$  single mutant and was indifferent in  $\Delta dksA$  mutant, when comparing with the wild type strain (Fig 3C and 3D, Left and Middle panel). As SpoT has been reported to regulate SPI-2 expression [40], we further confirmed that the Vac<sup>-</sup>Cyt<sup>-</sup> population of  $\Delta relAspoT$  shared a comparable metabolic profile as the one observed in the wild type strain (Fig 3D, Right panel). Together, these results suggested that (p)ppGpp stringent response mediated by SpoT but not RelA is required to restrict dormancy entry of *S. Typhimurium* within epithelial cells independent of the DksA regulon, while SPI-2 effector expression and secretion and Lon protease are dispensable.

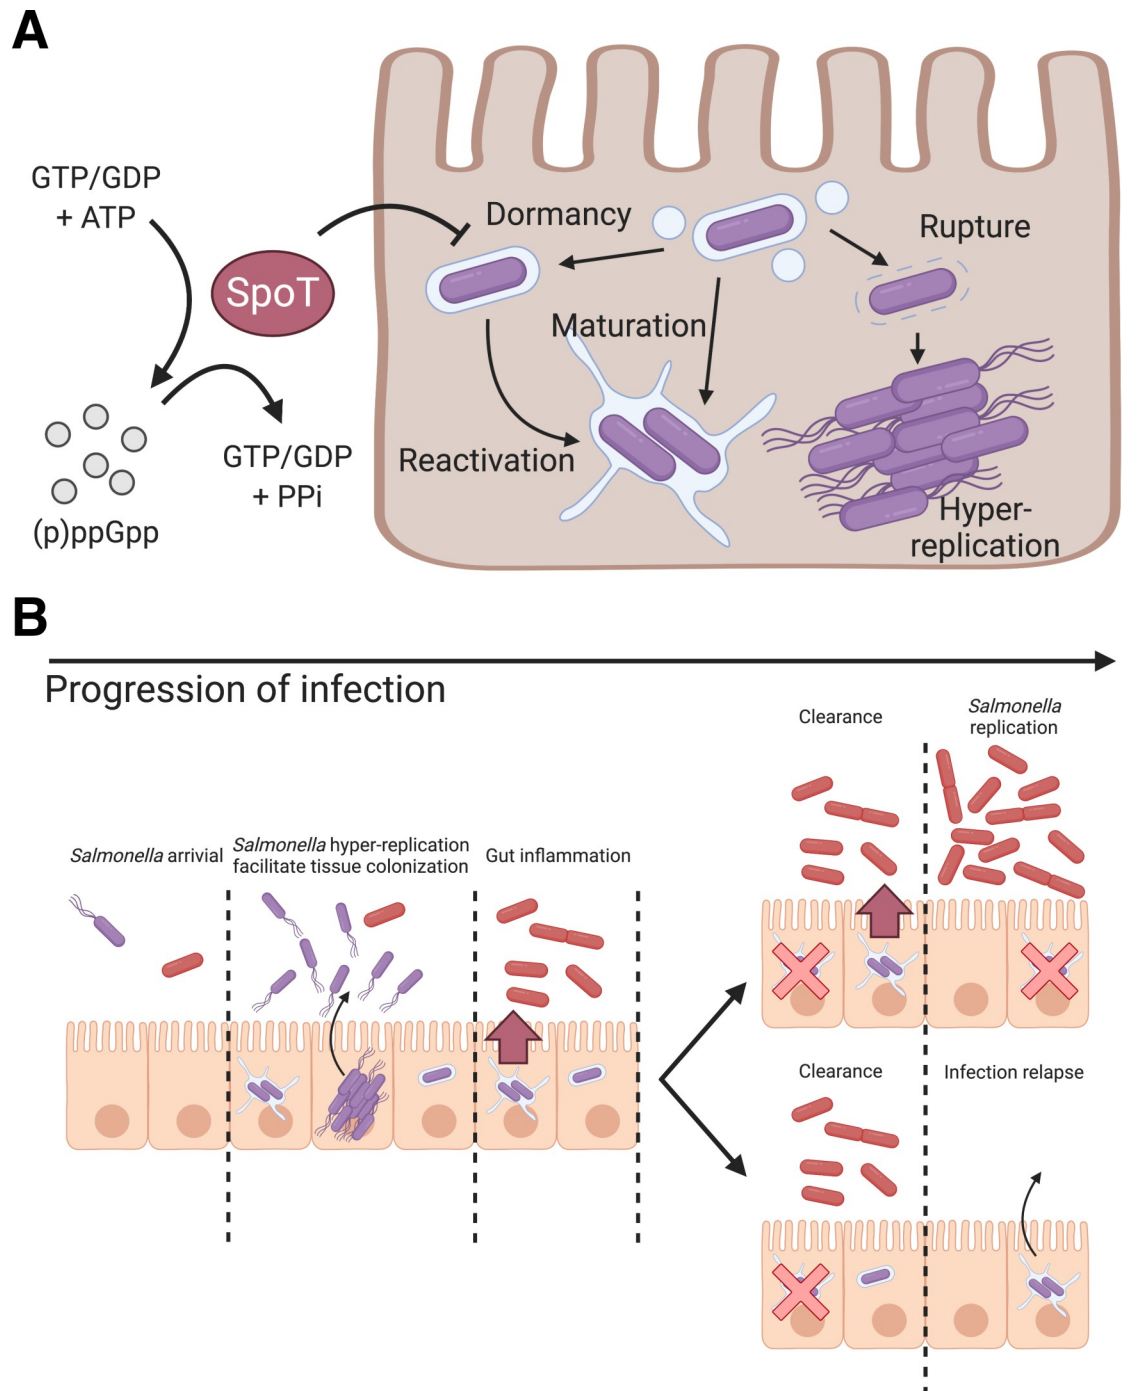

## Discussion

*S. Typhimurium* has been reported to survive in different host cells by adopting distinctive metabolic profiles, subcellular localizations and replication rates, which has also been proposed to account for various clinical complications. Herein, we report a dormant population of *S. Typhimurium* residing in a unique vesicular compartment in epithelial cells of the intestine. These dormant epithelial *S. Typhimurium* persist within host cells for a prolonged period. The SINA reporter system was instrumental for the discovery of enterocyte-borne dormant *S. Typhimurium* as it allowed the simultaneous depiction of the metabolism, subcellular localization and replication rate of the intracellular bacteria. The compatibility of the SINA system with microscopy and flow cytometry offers the opportunity for multi-omics analysis as well as high-throughput genetic and chemical screenings on genes and compounds that influence the bacterial pathophysiology.

The dormant *S. Typhimurium*, while remaining viable in the absence of SPI-2 expression, reside in a unique vesicular compartment distinct from the RAB5, RAB7, RAB11 or LAMP1-labelled SCV or the LC3-positive autophagosomes. Upon endocytosis, endosomes are either recycled or matured and eventually degraded via fusion with lysosomes. The SCV shares such a fate if T3SS2 effectors are not secreted to hijack the vesicular maturation pathway [34]. Therefore, we propose that dormant *S. Typhimurium* reside in a vesicular compartment idle to endocytic trafficking pathways that are independent of T3SS2 effectors. Such a diversion from default endocytic pathways is also observed by other bacterial pathogens, such as *Shigella*, and despite decades of research, no strong molecular markers have been identified for the short-lived *Shigella* containing vacuole [41]. The subsequent resumption of metabolism and SPI-2 expression potentially serve as a signal to reengage the dormant membrane-enclosed *S. Typhimurium* with endocytic trafficking pathways for remodeling the SCV into the conventional replicative niche (Fig 4A). The persistence of dormant *S. Typhimurium* in host cell for up to at least 7 days in our tested condition is also striking as the bacteria inside this vacuolar compartment are likely to have restricted access to the extracellular nutrients.

*S. Typhimurium* has been reported previously to enter dormant or persistent states within a modified SCV from a range of host cell types, including macrophages and fibroblasts [12,13]. Considering the presumably identical *S. Typhimurium* dormancy observed across the different cell models, there are substantial distinctions among the targeted host cell types in terms of the detection approaches and bacterial physiology. The first *S. Typhimurium* antibiotics-tolerant persisters were identified in macrophages using a dilution reporter on non-replicating *S. Typhimurium*, which enters dormancy and a viable-but-not-cultivable state upon entry [13].

**Fig 4. Schematic illustration of the role of (p)ppGpp alarmone pathway on *S. Typhimurium* dormancy in enterocytes and the proposed pathophysiological implication of *S. Typhimurium* dormancy in enterocytes.** (A) Schematic diagram of *S. Typhimurium* lifestyles and the regulatory role of SpoT on *S. Typhimurium* dormancy in human epithelial cells. *S. Typhimurium* can opt for three distinct lifestyles: cytosolic, vacuolar and dormant, which exhibits discernible subcellular localization, replication rate and metabolism. The entry of dormant state is negatively regulated by (p)ppGpp synthetase SpoT, while the regulatory mechanism on the dormancy exit remains to be determined. (B) Schematic diagram of *S. Typhimurium* infection progression in the gut epithelium. As *S. Typhimurium* reaches the intestinal epithelium, a portion of *S. Typhimurium* expresses T3SS1 (purple) to enter host cells and adopts various intracellular lifestyles. Distinct *S. Typhimurium* lifestyles support rapid tissue colonization and gut inflammation to increase competitiveness of luminal *S. Typhimurium* (red). (Top) Reactivation of dormant *S. Typhimurium* leads to prolonged gut inflammation that supports the continuous growth of *S. Typhimurium* at gut lumen. (Bottom) Dormant *S. Typhimurium* reactivates after the eradication of gut *S. Typhimurium*, which serves as the reservoirs of infection relapse.

<https://doi.org/10.1371/journal.ppat.1009550.g004>

The dormancy is regulated by the TA system toxin, TacT that halts protein translation and induces antibiotic persistence, where the *S. Typhimurium* subsequently exits dormancy and activates SPI-2 [16,29]. Slow growing *S. Typhimurium* were also identified in fibroblasts as early as 2003, where 0.001% of the bacteria survived until the end of the studied time course [12]. Studies in fibroblasts have deciphered major genetic determinants of bacterial persistence, however the underlying mechanisms of persistence with regards to bacterial viability, antibiotics, the pathological implication have been characterized in more depth in macrophages recently [11,42]. In the different infected host cells intracellular *S. Typhimurium* activates SPI-2 to remodel the SCV for replication and interacts with endocytic trafficking pathways. In fibroblasts, the SCV subsequently interacts with host autophagy, where the majority of the *S. Typhimurium* residing in the SCV are eradicated whereas the remaining *S. Typhimurium* were proposed to persist [11]. In epithelial cells, the reported *S. Typhimurium* dormancy by us is distinct from that in fibroblast and macrophage. They are different in the commencement of dormancy, the capacity to replicate and the SCV microenvironment [13]. The distinct niches of dormant *S. Typhimurium* may reflect cell-type specific vesicular trafficking, for example SPI-2 expression level and SCV maturation in these different target cells is not identical (S4, S8 and S9 Figs). It could also be possible that the way of entry impacts the development of dormant *S. Typhimurium*. Epithelial dormant *S. Typhimurium* is independent of Lon protease and is negatively regulated by SpoT, contrasting to that in macrophage that requires Lon protease, (p)ppGpp synthases RelA and SpoT [14,38]. The substantial difference between the *S. Typhimurium* dormancy sheds light on their potentially diverge pathophysiological implications as well as the molecular cue and mechanism that signal the establishment and exit of dormancy. The extensive work on TA systems and *S. Typhimurium* physiology in fibroblasts would serve as significant groundwork for the further studies of enterocyte-borne dormant *S. Typhimurium* [42]. It will be interesting to investigate why these regulatory modules are differentially involved in the formation of dormant *S. Typhimurium* in the different cell types, and whether the distinct niche impacts their expression and implication.

(p)ppGpp, is a bacterial alarmone that functions as a key regulator of bacterial physiology. The (p)ppGpp-mediated stringent response has been closely associated with antibiotic persistence via inhibition of protein synthesis and transcription reprogramming [43–45]. The persistent *S. Typhimurium* in macrophages is dependent on a (p)ppGpp-Lon protease-Class II TA systems axis, where TacT leads to a halt in protein translation [16]. In non-pathogenic *E. coli* and *S. Typhimurium* models, the loss of Lon and its downstream regulated TA systems leads to a diminished antibiotic persister formation due to the inactivity of toxins [46]. In our findings, the dormant phenotype is negatively regulated by (p)ppGpp synthases SpoT and partially by RelA, but independent of DksA and Lon protease-mediated pathways (Fig 4A). Our finding contrasts the current understanding on the role of stringent response on bacterial persistence, where stringent response is activated by various stress signals and (p)ppGpp synthesis would act on its molecular target to achieve persistence. Therefore, we suggest that bifunctional SpoT is required while monofunctional RelA is dispensable in *S. Typhimurium* dormancy in enterocytes, which echoes the previous report on the requirement of SpoT but not RelA in *S. Typhimurium* invasion and colonization of an *in vivo* model [39]. The essence of SpoT but not RelA for *S. Typhimurium* dormancy could suggest that either or both the (p)ppGpp hydrolysis and synthase function is required, or *relA* is not expressed during the course of infection. Considering that *S. Typhimurium* dormancy is independent of DksA and Lon, it implies that dormancy is likely to be mediated by pathways independent of DksA transcription reprogramming and Lon protease-mediated degradation. As RelA and SpoT function to convert GDP and GTP to (p)ppGpp, and SpoT hydrolyzes (p)ppGpp to give GTP/GDP and pyrophosphate, an imbalance of RelA/SpoT activity upsets the bacterial energy status, which could

potentially act as a cue for dormancy. As dormant *S. Typhimurium* do not co-exist with *S. Typhimurium* of other lifestyles (Fig 2F), the host cell status is also implied to serve a regulatory role on *S. Typhimurium* dormancy.

With the traits we uncovered in the dormant *S. Typhimurium* within epithelial cells, this population could represent the intestinal persister, given the close association between bacterial dormancy and antibiotic persistence. Besides the proposed antibiotic persistence and horizontal gene transfer, the physiological features of enterocyte-borne dormant *S. Typhimurium* could also provide two plausible benefits to *S. Typhimurium* colonization of the host gut [47] (Fig 4B): 1) Dormancy and delayed expression of SPI-2 allow *S. Typhimurium* to evade cellular immunity during early invasion and to provide a sustained and extended SPI-2 expression at tissue scale, where *S. Typhimurium* reactivated from dormancy supports SPI-2 expression as classic vacuolar *S. Typhimurium* is eradicated. The sustained SPI-2 expression fuels gut inflammation to release electron acceptors for *S. Typhimurium* survival benefits in the gut lumen [33]. 2) Persistent *S. Typhimurium* resided within the intestinal tissue serves as the source of subsequent infection relapse or systemic spread, where the maximum duration of persistence and molecular cues for reactivation remain to be elucidated (Fig 4B).

## Materials and methods

### Mammalian cell culture

HeLa cervical adenocarcinoma cells, Caco-2 colorectal adenocarcinoma cells, 3T3 mouse fibroblasts and THP-1 acute monocytic leukemia cells were purchased from American Type Culture Collection (ATCC) and used within 20 passages of receipt. HeLa cells and 3T3 cells were cultured in Dulbecco's Modified Eagle Medium (DMEM, high glucose, GlutaMAX Supplement, ThermoFisher) containing 10% (v/v) heat-inactivated fetal bovine serum (FBS, Sigma) and incubated at 37°C with 5% CO<sub>2</sub> and 100% humidity. Caco-2 cells were cultured in DMEM containing 10% FBS, 1% Non-essential amino acids (Gibco), 1% HEPES (Gibco), 1% Penicillin/Streptomycin (Gibco) and incubated at 37°C with 5% CO<sub>2</sub> and 100% humidity. THP-1 cells were cultured in RPMI-1640 medium (ThermoFisher) containing 10% FBS and incubated at 37°C with 5% CO<sub>2</sub> and 100% humidity. HeLa and 3T3 cells were seeded in 12-well tissue-culture treated plates (Corning Costar) at a density of 9x10<sup>4</sup> cells/well 48 hours prior to infection. Caco-2 cells were polarized using Corning BioCoat Assay System (Corning) following manufacturer's protocol. THP-1 cells were seeded in 12-well tissue-culture treated plates at a density of 9x10<sup>4</sup> cells/well 96 hours prior to infection, and differentiated in 50 µg/mL phorbol 12-myristate 13-acetate (PMA, Sigma) for 24 hours, and incubated in RPMI-1640 + 10% for 72 hours. For immunofluorescence staining, HeLa cells were seeded on UV-treated glass coverslips (Marienfeld) in 12-well plates 48 hours prior to infection. For cell sorting experiments, HeLa cells were seeded in 10 cm tissue-culture treated dishes (Corning Costar) at a density of 1.8x10<sup>6</sup> cells/well 48 hours prior to infection.

### Bacterial strains

Bacterial strains and plasmids used in this study are listed in S1 and S2 Tables, respectively. All mutants were constructed using bacteriophage λ red recombinase system from parental strain *S. Typhimurium* strain SL1344 using primers listed in S3 Table [48]. HA-tagged T3SS2 effector strains were generated by transducing JL129 with P22 phage lysate (a generous gift from Stéphane Méresse, Centre d'Immunologie de Marseille-Luminy, France). Bacteria were cultured in Lysogeny broth (LB) supplemented with appropriate antibiotics, where necessary (Ampicillin 100 µg/mL; Kanamycin 50 µg/mL).

## Plasmid construction

The replication rate module, *Timer<sup>bac</sup>* is a generous gift from Dr. Dirk Bumann (University of Basel, Switzerland) [20]. To construct the localization module, *tagBFP* was amplified from pHRdSV40-NLS-dCas9-24xGCN4\_v4-NLS-P2A-BFP-dWPRE using primers *tagBFP\_fw* and *tagBFP\_rv*, and replaced the GFP in pM973 to yield vacuolar module (pP<sub>ssaG</sub>-*tagBFP*) [19,49]. For the cytosolic module (pP<sub>uhpT</sub>-*smURFP*), *smURFP-HO-1* and *uhpT* promoters were amplified from pBAD *smURFP-HO-1* (*smURFP\_fw* and *smURFP\_rv*) and *S. Typhimurium* gDNA (*uhpT\_fw* and *uhpT\_rv*), respectively, and replaced the *sfGFP* and *mxiE* promoter in pTSAR1 [50,51]. The vacuolar (*Vac\_fw* and *tagBFP\_rv*) and cytosolic (*uhpT\_fw* and *Cyt\_rv*) modules were amplified and inserted into *EcoRV* and *SmaI* sites, respectively, of pBlueScript II KS (+) to generate pSINA-int. The localization module on pSINA-int was excised and inserted between *SaII* and *SphI* sites of pBR322 *Timer<sup>bac</sup>* to yield pSINA1.1. pSINA1.4 was generated by replacing *Timer<sup>bac</sup>* with *GFP* in pBR322 *Timer<sup>bac</sup>* and inserted the vacuolar module at the *SaII* and *SphI* sites. pSINA1.5 was generated by inserting the amplified inducible *smURFP* cassette (*Ara\_fw* and *Ara\_rv*) and vacuolar cassette between the *SaII* and *EagI* sites of pBR322 *Timer<sup>bac</sup>*. pSINA1.7 was constructed by reverting *Timer<sup>bac</sup>* to *DsRed* by site-directed mutagenesis using *DsRed\_fw* and *DsRed\_rv*. pBAD *hilA* was generated by inserting the amplified *hilA* (*hilA\_fw1* and *hilA\_rv1*) between the *BamHI* and *PmeI* sites of pBAD *smURFP-HO-1*. The inducible *hilA* cassette was amplified using primer *hilA\_fw2* and *hilA\_rv2* and inserted into the *EcoRV* site of pSINA1.1 to generate pSINA1.9.

## Bacterial infections

Bacteria strains were streaked from glycerol stock on LB agar plates with appropriate antibiotics 2 days prior to infection. Three bacterial colonies were picked for overnight culture in LB medium supplemented with 0.3 M NaCl with shaking at 37°C. 150 µL overnight culture was subculture in 3 mL LB + 0.3 M NaCl (1:20 dilution) with shaking at 37°C for 3 h. For strains harboring pSINA1.9, 0.1% L-arabinose was supplemented to the subculture 1 h before harvest. Bacteria were harvested with centrifugation (1 mL, 6000 x g, 1 min, RT), washed once in 1 x PBS and resuspended in DMEM with no FBS. HeLa cells were infected at a MOI of ~100 for 25 min at 37°C. Extracellular bacteria were removed and washed with 1 x PBS (5X). Cells were then incubated in DMEM + 10% FBS for 1 h, washed with 1 x PBS (3X), incubated in DMEM + 10% FBS for 2 h, washed with 1 x PBS (3X) and then incubated in DMEM + 10% FBS supplemented with 10 µg/mL gentamicin for the remaining time course of the infection.

## Flow cytometry

At designated time points, cells were washed with 1 x PBS (1X) and detached with 0.05% Trypsin for 5 min at 37°C. Detached cells were mixed with equal volume of DMEM + 10% FBS, passed through 40 µm strainer and collected by centrifugation (500 x g, 5 min, 4°C). Cell pellets were dislodged and fixed in 4% PFA (15 min, RT). Fixed cells were washed with 1 x PBS (2X) and resuspended in 200 µL 1 x PBS for further analysis. For digitonin permeabilization experiment, cells were permeabilized with 45 µg/mL digitonin (1 min, RT) or 0.25% saponin (30 min, RT), then washed and stained with anti-*S. Typhimurium* primary antibody and Alexa488-conjugated goat anti-rabbit secondary antibody [21]. The fluorescence intensities of the samples were assayed with LSR Fortessa (BD) (*tagBFP* Ex: 405 nm Em: 450/50 nm; *Timer<sup>510</sup>* Ex: 488 nm Em: 525/50 nm; *Timer<sup>580</sup>* Ex: 562 nm Em: 582/15 nm; *smURFP* Ex: 633 nm Em: 670/30 nm) and analyzed with FlowJo (v10.0.4). The recorded events were gated according to the strategy described (S2 Fig).

### Cell sorting

At designated time points, cells were washed with 1 x PBS (1X) and detached with 0.05% Trypsin for 5 min at 37°C. Detached cells were mixed with equal volume of DMEM + 10% FBS, passed through 40 µm strainer and collected by centrifugation (500 x g, 5 min, 4°C). Cells were washed with 1 x PBS (1X) and resuspended in DMEM + 10% FBS supplemented with 10 µg/mL gentamicin. SYTOX Green (ThermoFisher) was supplemented to differentiate dead cells when necessary. Cells were sorted with Aria III (BD) (tagBFP Ex: 405 nm Em: 450/50 nm; Timer<sup>510</sup> and SYTOX Green Ex: 488 nm Em: 530/30 nm; Timer<sup>580</sup> Ex: 561 nm Em: 586/15 nm; smURFP Ex: 633 nm Em: 660/20 nm) to collect uninfected cells, infected cells with dormant or SPI-2 *S. Typhimurium* populations. The recorded events were gated according to the strategy described (S2 Fig).

### Immunofluorescence microscopy

Cells seeded on coverslips were washed with 1 x PBS (1X) and fixed in 4% PFA (8 min, RT). After washing with 1 x PBS (3X), cells were permeabilized and blocked in 1 x PBS, 20% FBS, 0.25% saponin (30 min, RT). Coverslips were washed with 1 x PBS (3X) and incubated with anti-RAB5, anti-RAB7, anti-RAB11, anti-LC3 or anti-LAMP1 primary antibodies and phalloidin-rhodamine diluted in 1 x PBS, 2% FBS (60 min, RT), and then washed with 1 x PBS (3X) and incubated with Cy5-conjugated goat anti-rabbit secondary antibodies diluted in 1 x PBS, 2% FBS (60 min, RT). Stained coverslips were then washed with 1 x PBS (3X) and mounted on SuperFrost Plus microscope slides (Thermo Scientific) with ProLong Gold Anti-fade Mountant without DAPI (Invitrogen). Samples were imaged with Perkin Elmer Ultra-view confocal spinning disk microscope equipped with Volocity software and a 20X/1.3 NA air objective. Images were analyzed with FIJI (NIH) [52] and figures were prepared using Inkscape (v1.0.1).

### Colony forming unit plating

Infected HeLa cells were enriched by cell sorting, where 1000 infected cells were sorted for each sample. The cells were then collected by centrifugation at 500 x g for 5 min, and subsequently lysed in 0.1% Triton X-100 for 5 min at room temperature. The lysed cells were then serially diluted and plated on LB agar plates with appropriate antibiotics.

### Dormant *S. Typhimurium* persistence assay

Infected HeLa cells harboring dormant *S. Typhimurium* were enriched by cell sorting using the gate Vac<sup>-</sup>Cyt<sup>-</sup>, and plated on 12-wells plates in DMEM + 10% FBS + Gen<sup>10</sup>. The medium was replaced with fresh DMEM + 10% FBS + Gen<sup>10</sup> to avoid the growth of *S. Typhimurium* being released from dead cells. Cells were harvested at 24 h and 168 h pi for analysis and CFU plating.

### Ciprofloxacin survival assay

A final concentration of 10 µg/mL of ciprofloxacin (CIP) were supplemented to the cell culture medium of the infected cells at 3 h pi. The cells were harvested at 6 h pi for cell sorting and CFU plating. CIP was administered at 3 h pi, which offered sufficient time for the infected population to differentiate into Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> for downstream enrichment of Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> populations.

## Serial sectioning transmission electron microscopy

At 6 h pi, infected HeLa cells harboring Vac<sup>-</sup>Cyt<sup>-</sup> *S. Typhimurium* were harvested by cell sorting. Enriched cells were allowed to adhere on specific dishes (MatTek) pre-coated with 50 mg/ml fibronectin (Sigma) for 3 hours. For EM sample preparation, the adhered cells were fixed with 4% PFA (EMS), 2.5% glutaraldehyde (Sigma-Aldrich) in 0.2 M HEPES for 1 hour at room temperature. Fixed samples were washed with 1 x PBS for three times, and position of interest were defined by fluorescent light microscopy. For further sample preparation, the fixed cells washed three times by the addition of fresh 0.1 M Caco buffer (pH 7.2) and post-fixed in 1% osmium (EMS) in 0.1 M Caco buffer (pH 7.2) enriched with 1.5% potassium ferrocyanide (Sigma-Aldrich) for 1 h. After three washes in 0.1M Caco buffer, samples were incubated in 0.2% of Tannic acid in water for 30 min at room temperature. Samples are post-fixed for a second time in 1% of osmium for 1 h, washed with water and incubated in 2% uranyl acetate dissolved in 25% ethanol for 1 h. Samples were then gradually dehydrated in an ethanol (Sigma-Aldrich) series ranging from 50% to 100%. Samples were embedded in PolyBed812 resin (EMS), followed by polymerization for 48 h at 60°C. The resin embedded samples were removed from the dishes after gentle heating.

For the correlative microscopy, the region of interest was determined thanks to landmarks printed below embedded samples. Embedded cells were sectioned with an ultramicrotome (Leica, UC7) with 70 nm thickness. Thin serial sections were collected on a single slot grid (Agar scientific). Serial sections were observed with a transmission electron microscope TEM Technai T12 (ThermoFisher) at 120kV.

## Statistical analysis

Unless further specified in the figure legend, data were analyzed for statistical significance with a Mann-Whitney test using Prism 8.0 (GraphPad). *P* value of  $\leq 0.05$  is considered statistically significant. \**P* < 0.05, \*\**P* < 0.01, \*\*\* *P* < 0.001, \*\*\*\* *P* < 0.0001, ns: not significant/ *P*  $\geq 0.05$ .

**S3 Fig. Localization modules indicate subcellular localization of *S. Typhimurium*.** (A) Gating strategy for applying SINA1.7 for digitonin assay. HeLa cells were infected with SINA1.7--harboring wild type *S. Typhimurium*, and harvested at 6 h pi for analysis by flow cytometry. The events were first gated for “Cells” to remove cell debris and subsequently gated for “uninfected” and “infected” based on DsRed signal. The “infected” events were subsequently gated for Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> on tagBFP::SPI-2 vs smURFP::cytosolic plot. The fluorescence profiles FITC::S. Typhimurium (after immunostaining using anti-*S. Typhimurium* antibody) of Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> and “uninfected” were plotted as overlay histograms. The gating strategy displays a positive control sample treated with saponin. (B) Schematic diagram for the constructions of the SINA derivative SINA1.7, where Timer<sup>bac</sup> was replaced with DsRed as compared to SINA1.1. (C) Digitonin assay on SINA-1.7 harboring wild type *S. Typhimurium*-infected HeLa cells at 6 h pi, signal intensities of uninfected (black), Vac<sup>-</sup>Cyt<sup>-</sup> (red), Vac<sup>+</sup>Cyt<sup>-</sup> (blue) and Vac<sup>+</sup>Cyt<sup>+</sup> (green) populations immunostained against anti-*S. Typhimurium*. (D) Digitonin assay on SINA-1.7 harboring wild type *S. Typhimurium* infected HeLa cells at 6 h pi, signal intensity of Vac<sup>-</sup>Cyt<sup>-</sup> population unpermeabilized (black, negative control), permeabilized with digitonin (red) and saponin (maroon, positive control). (E) Digitonin assay on SINA-1.7 harboring wild type *S. Typhimurium* infected HeLa cells at 6 h pi, signal intensity of Vac<sup>+</sup>Cyt<sup>-</sup> population unpermeabilized (black, negative control), permeabilized with digitonin (blue) and saponin (navy, positive control). (F) Digitonin assay on SINA-1.7 harboring wild type *S. Typhimurium* infected HeLa cells at 6 h pi, signal intensity of Vac<sup>+</sup>Cyt<sup>+</sup> population unpermeabilized (black, negative control), permeabilized with digitonin (green) and saponin (dark Green, positive control).

(TIF)

**S4 Fig. SINA1.1 performance in HeLa cells at 2 h, 4 h and 6 h pi.** HeLa cells were infected with wild type *S. Typhimurium* harboring SINA1.1. (A) Infected cells were harvested and analyzed at time intervals of 2 h, 4 h and 6 h pi. (Left) Timer<sup>bac</sup> profile of total cells at 2 h (top), 4 h (middle) and 6 h (bottom) pi in HeLa cells. (Right) Fluorescence output of the localization module of infected cells at 2 h (top), 4 h (middle) and 6 h (bottom) pi in HeLa cells. (B-C) Time-lapse microscopic acquisition of the *S. Typhimurium* intracellular lifestyle. Representative images of SINA1.1 signal output of vacuolar (B) and cytosolic (C) *S. Typhimurium*. Scale bars are 10 μm.

(TIF)

**S5 Fig. *S. Typhimurium* exhibits distinct replication rates and metabolism in HeLa cells.**

HeLa cells were infected with SINA1.1-harboring *S. Typhimurium* and harvested at 6 h pi for analysis by flow cytometry. The three infected cell populations, Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> on tagBFP::SPI-2 vs smURFP::cytosolic plot were backgated on Timer<sup>580</sup> vs Timer<sup>510</sup> plot. Timer<sup>580</sup> and Timer<sup>510</sup> intensities were extracted from each event. (A) Quantification of Green:red ratio of Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> population in Timer<sup>bac</sup> plot at 6 h pi. Green:red ratios were calculated by dividing Timer<sup>510</sup> by Timer<sup>580</sup> values, and plotted against infected cell populations. (B) Quantification of the slope of the best-fitted line of Vac<sup>-</sup>Cyt<sup>-</sup>, Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>+</sup>Cyt<sup>+</sup> population in Timer<sup>bac</sup> plot at 6 h pi. For each population, a best-fitted line was plotted on the Timer<sup>580</sup> vs Timer<sup>510</sup> plot to extract the slopes for each infected cell populations. At least a total of 1000 events of infected cells were analyzed by flow cytometry in

triplicate experiments. The bars represent the mean value, unpaired t-tests were carried out, \* $P < 0.05$ , \*\*\*\* $P < 0.0001$ , ns: not significant.

(TIF)

**S6 Fig. Dormant *S. Typhimurium* are observed as early as 2 h pi in HeLa cells.** HeLa cells were infected with SINA1.1-harboring *S. Typhimurium*, and harvested at 1 h, 2 h and 3 h pi for analysis by flow cytometry. The infected cells were gated and the fluorescence profiles of vacuolar submodule  $P_{ssaG}$ -tagBFP at 1 h (black), 2 h (red) and 3 h (blue) pi were plotted as overlaying histograms.

(TIF)

**S7 Fig. Performance of SINA1.1 in Caco-2 cells.** Polarized Caco-2 monolayers were infected with SINA1.1-harboring *S. Typhimurium* and harvested at 1 h and 6 h pi for analysis by flow cytometry. (Left)  $\text{Timer}^{\text{bac}}$  profile of  $\text{Vac}^- \text{Cyt}^-$  (red) and  $\text{Vac}^+ \text{Cyt}^-$  (blue) populations and total cells (black) at 1 h (top) and 6 h (bottom) pi in Caco-2 cells. (Right) Distribution of  $\text{Vac}^- \text{Cyt}^-$  and  $\text{Vac}^+ \text{Cyt}^-$  populations at 1 h (top) and 6 h (bottom) pi in polarized Caco-2 cells.

(TIF)

**S8 Fig. Performance of SINA1.1 in 3T3 cells.** 3T3 cells were infected with SINA1.1-harboring *S. Typhimurium* and harvested at 1 h, 6 h and 24 h pi for analysis by flow cytometry. (Left)  $\text{Timer}^{\text{bac}}$  profile of  $\text{Vac}^- \text{Cyt}^-$  (red),  $\text{Vac}^+ \text{Cyt}^-$  (blue) and  $\text{Vac}^+ \text{Cyt}^+$  (green) populations and total cells (black) at 1 h (top), 6 h (middle) and 24 h (bottom) pi in 3T3 cells. (Right) Distribution of  $\text{Vac}^- \text{Cyt}^-$ ,  $\text{Vac}^+ \text{Cyt}^+$  and  $\text{Vac}^+ \text{Cyt}^+$  populations at 1 h (top), 6h (middle) and 24 h (bottom) pi in 3T3 cells.

(TIF)

**S9 Fig. Performance of SINA1.1 in THP-1 cells.** Differentiated THP-1 cells were infected with SINA1.1-harboring *S. Typhimurium* and harvested at 1 h, 6 h and 24 h pi for analysis by flow cytometry. (Left)  $\text{Timer}^{\text{bac}}$  profile of  $\text{Vac}^- \text{Cyt}^-$  (red) and  $\text{Vac}^+ \text{Cyt}^-$  (blue) populations and total cells (black) at 1 h (top), 6 h (middle) and 24 h (bottom) pi in THP-1 cells. (Right) Distribution of  $\text{Vac}^- \text{Cyt}^-$  and  $\text{Vac}^+ \text{Cyt}^-$  populations at 1 h (top), 6 h (middle) and 24 h (bottom) pi in differentiated THP-1 cells.

(TIF)

**S10 Fig. Serial sectioning TEM determines the subcellular localization of  $\text{Vac}^- \text{Cyt}^-$  *S. Typhimurium*.** (A) Brightfield and fluorescent microscopy image of region of interest on Mat-Tek dish. (B) Brightfield and fluorescent microscopy image of cells of interest harboring  $\text{Vac}^- \text{Cyt}^-$  *S. Typhimurium*. (C) TEM image of cell of interest in labelled region from (B). (D) Magnified TEM image of labelled region from (C).

(TIF)

**S11 Fig. Infected cells harboring dormant *S. Typhimurium* are viable.** HeLa cells were infected with SINA1.7 harboring *S. Typhimurium*, harvested at 6 h pi and stained with SYTOX Green and analyzed by flow cytometry. The infected cells were gated and the fluorescence profiles of SYTOX Green in uninfected cell (black),  $\text{Vac}^- \text{Cyt}^-$  (red),  $\text{Vac}^+ \text{Cyt}^-$  (blue) and  $\text{Vac}^+ \text{Cyt}^+$  (green) were plotted as offset histograms.

(TIF)

**S12 Fig. Ectopic expression of *hilA* rescues the loss of invasiveness.** HeLa cells were infected with various *S. Typhimurium* strains and harvested at 6 h pi for flow cytometry analysis. The losses of invasiveness in  $\Delta dksA$  and  $\Delta relAspoT$  mutants are rescued by ectopic expression of *hilA* from the arabinose inducible cassette in SINA1.9. At least a total of 1000 events of infected

cells were analyzed by flow cytometry in triplicate experiments. The bars represent the mean value, unpaired t-test was carried out, \*\*\*\* $P < 0.0001$ .

(TIF)

**S1 Movie. Connected to Fig 1D: Time-lapse microscopy shows the fluorescence signal output from SINA1.1 in Vac<sup>+</sup>Cyt<sup>-</sup> intracellular *S. Typhimurium* population.** Brightfield and fluorescence output of Timer<sup>bac</sup>, P<sub>ssaG</sub> and P<sub>uhpT</sub> from SINA1.1-harboring *S. Typhimurium* exhibiting Vac<sup>+</sup>Cyt<sup>-</sup> profile. Images were taken every 15 min starting from 1 h pi. (AVI). (AVI)

**S2 Movie. Connected to Fig 1D: Time-lapse microscopy shows the fluorescence signal output from SINA1.1 in Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>-</sup>Cyt<sup>+</sup> intracellular *S. Typhimurium* population.** Brightfield and fluorescence output of Timer<sup>bac</sup>, P<sub>ssaG</sub> and P<sub>uhpT</sub> from SINA1.1-harboring *S. Typhimurium* exhibiting Vac<sup>+</sup>Cyt<sup>-</sup> and Vac<sup>-</sup>Cyt<sup>+</sup> profiles. Images were taken every 15 min starting from 1 h pi. (AVI). (AVI)

**S3 Movie. Connected to Fig 1D: Time-lapse microscopy shows the fluorescence signal output from SINA1.1 in Vac<sup>-</sup>Cyt<sup>-</sup> intracellular *S. Typhimurium* population.** Brightfield and fluorescence output of Timer<sup>bac</sup>, P<sub>ssaG</sub> and P<sub>uhpT</sub> from SINA1.1-harboring *S. Typhimurium* exhibiting Vac<sup>-</sup>Cyt<sup>-</sup> profile. Images were taken every 15 min starting from 1 h pi. (AVI). (AVI)

## Acknowledgments

We thank the members of the Dynamics of Host-Pathogen Interactions Unit for the constructive comment and discussion. We are grateful for the generous plasmid gift from D. Bumann, and we acknowledge S. Méresse for the P22 lysates of tagged PipB2-2HA.
