11 SUMMARY

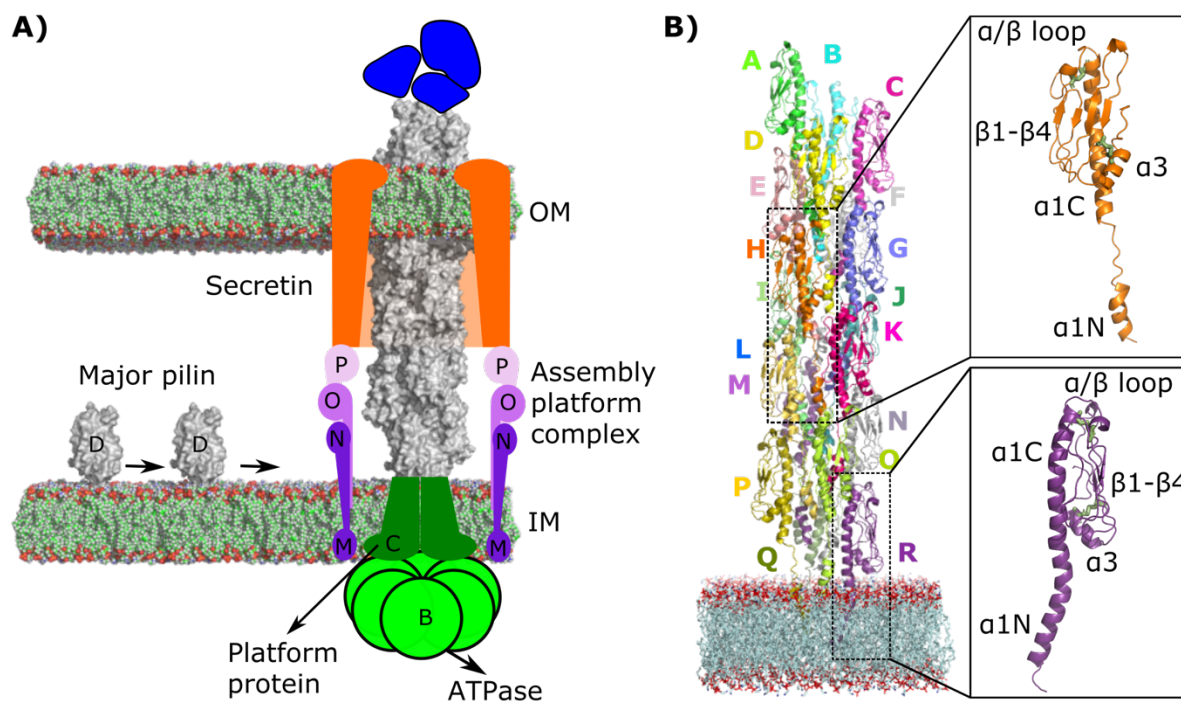

12 Type IV pili (T4P) are distinctive dynamic filaments at the surface of many bacteria that can rapidly extend, retract and
13 withstand strong forces. T4P are important virulence factors in many human pathogens, including Enterohemorrhagic
14 *Escherichia coli* (EHEC). The structure of the EHEC T4P has been determined by integrating Nuclear Magnetic Resonance
15 (NMR) and cryo-electron microscopy data. To better understand pilus assembly, stability and function, we performed a total
16 of 108 μ s all-atom molecular dynamics simulations of wild-type and mutant T4P. Extensive characterization of the
17 conformational landscape of T4P in different conditions of temperature, pH and ionic strength was complemented by targeted
18 mutagenesis and biochemical analyses. Our simulations and NMR experiments revealed a conserved set of residues defining
19 a novel calcium-binding site at the interface between three pilin subunits. Calcium binding enhanced T4P stability *ex vivo* and
20 *in vitro*, supporting the role of this binding site as a potential pocket for drug design.

21 INTRODUCTION

22 In bacteria, multiple molecular machineries perform a wide variety of biological functions necessary for their survival, social
23 organization, motility, and capacity of infecting host cells. Bacterial interactions with their environment often rely on surface
24 polymers called pili, which are assembled through a regular repetition of one or few protein subunits called pilins. In some
25 cases, pilins are irreversibly or covalently linked to each other, building fibers with high stability and mechanical resistance.
26 This is the case of type I pili from Gram-negative (Hospenthal, Costa, and Waksman 2017) and sortase-dependent pili from
27 Gram-positive bacteria (Kang and Baker 2012). Other pili are maintained by noncovalent interactions between subunits to
28 combine mechanical strength with flexibility and dynamics. Remarkable representatives of this class are type IV pili (T4P),
29 most notably the T4aP subclass that are able to rapidly assemble and disassemble (Craig, Forest, and Maier 2019). T4P
30 dynamics is crucial for their biological functions, which include adhesion to host cells, twitching motility, DNA uptake, protein
31 secretion, and microcolony formation. These fibers can reach several micrometers in length and range between 6-9 nm in
32 diameter. The machinery that assembles T4P is formed by several protein sub-complexes that span the bacterial envelope
33 (**Figure 1a**). T4P are anchored in the inner membrane (IM) and extend beyond the outer membrane (OM) of Gram-negative
34 bacteria through a channel called the secretin. Dedicated ATPases at the cytoplasmic base of the complex transmit motions to
35 the assembly platform IM complex to drive fiber extension and retraction.

36 T4Ps are present in Enterohemorrhagic *Escherichia coli* (EHEC), an important human pathogen. The major pilin PpdD (or
37 HcpA) is one of the EHEC virulence factors (Xicohtencatl-Cortes et al. 2007) and its sequence is highly conserved in
38 Enterobacteriaceae (Luna Rico et al. 2019). The structure of the periplasmic domain of EHEC PpdD determined by NMR
39 (Amorim et al. 2014; Bardiaux et al. 2019), combined with the cryo-EM density map of the EHEC pilus at 8 Å resolution, led
40 to an atomistic model of the T4P filament (Bardiaux et al. 2019). A variety of structural data is available for other T4P, with
41 major contributions coming from cryo-EM (Wang et al. 2017; Kolappan et al. 2016; Hartung et al. 2011; Craig et al. 2006;
42 Craig et al. 2003; Parge et al. 1995). Despite the recent progress in cryo-EM and integrative structural biology, the high
43 flexibility of this family of fibers often limits the resolution of the structure. Modeling is therefore a necessary step in structure
44 determination, even for the highest resolution cryo-EM maps obtained to date, such as those of the *Thermus thermophilus* T4P
45 (Neuhaus et al. 2020). Moreover, given the T4P flexibility and ability to rapidly extend and retract, a single structural model

46 is not sufficient to fully understand their behavior, nor to design new ways to regulate and interfere with their functions. A
47 crucial ingredient currently missing is a comprehensive and accurate characterization of the dynamic properties of these
48 systems.

49
50 **Figure 1. Schematic representation of the EHEC T4P assembly system.** (A) Major pilin PpdD (gray) and minor pilins (blue) are depicted.
51 Cytoplasmic ATPases (B, light green) transmit the conformational changes to the IM platform protein (C, dark green) and to the assembly
52 complex (M, N, O, P, purple shades), which is connected with the secretin (orange) in the OM. (B) The starting structure for the MD
53 simulations is depicted. T4P subunits (A-R) are shown as cartoon models in different colors. The POPE membrane atoms are shown with
54 spheres colored in green (carbon), red (oxygen), and blue (nitrogen). The insets highlight the structure of two subunits with two conformations
55 for the linker: as a coil (in orange), and modelled as a helix (in purple). The disulfide bonds are highlighted with green sticks.

56 The main objective of the present study is to investigate internal dynamics of T4P to be able to propose strategies that regulate
57 T4P behavior by directly targeting the pilus. With the aim to reach a deeper understanding of T4P dynamics and its functional
58 role, we performed a total of 108 μ s all-atom molecular dynamics (MD) simulations of EHEC pili. This allowed us to reveal,
59 at atomistic detail, the network of dynamic interactions between subunits and the role of different regions in modulating
60 filament flexibility. This in-depth characterization of the conformational dynamics can also help explain the physical-chemical
61 basis of the molecular mechanisms behind the filament formation. We also analyzed the effect of specific structural features
62 of pilin subunits on pilus dynamics and stability. While most T4a pilins have one disulfide bridge, defining the C-terminal loop
63 (Amorim et al. 2014), and homologous type II secretion pseudopilins have none, enterobacterial T4P has an additional,
64 conserved disulfide bond connecting the N-terminal α helix with the globular domain (Luna Rico et al. 2019). In this study,
65 by combining *in silico* analysis with mutagenesis and biochemical assays, we analyzed the effects of these disulfide bonds on
66 pilin stability and dynamics, as well as on the assembly of the pilus. Finally, we studied the role of ions. Other filaments of the
67 T4P superfamily, such as archaeal flagella and the type II secretion pseudopili, are stabilized by calcium or other cations
68 (Meshcheryakov et al. 2019; Lopez-Castilla et al. 2017; Korotkov et al. 2009), however their effect on T4aP has not been
69 investigated. Here, by using NMR we showed that PpdD subunit binds calcium and identified the residues involved in this
70 interaction. We combined MD analysis with targeted mutagenesis and functional assays to characterize the interaction of
71 calcium and other ions within the assembled pilus and understand their role in fiber biogenesis and dynamics. Together, our
72 MD analysis and *ex vivo* and *in vitro* assays allowed us to identify the key structural elements required for the stability and
73 assembly of T4P.

74 RESULTS

75 We performed a series of all-atom MD simulations listed in **Table 1**. To elucidate the role of ions in pilus dynamics, we carried
76 out MD simulations of T4P in the absence of ions and in the presence of Ca^{2+} , Na^+ , Mg^{2+} , Mn^{2+} and at different salt

77 concentrations. The effect of Ca^{2+} was studied at different temperatures: 36.85°C (310 K), 60°C (333.15 K) and 80°C (353.15
78 K). We also evaluated the role of specific subunit features in pilus stability and function, notably the two disulfide bridges
79 present in PpdD (by analyzing double substituted PpdD variants C50C60S and C118C130S), and the fully conserved residue
80 E5 (variant E5A). Finally, we studied the effects of different histidine protonation states for the essential residue H54: *i*) HSE
81 (ϵ), *ii*) HSD (δ), and *iii*) HSP ($\epsilon-\delta$). In total, we performed 108 μs MD simulations of 16 different systems, with three replicates
82 for each. For all analyses, we considered the union of the results from the replicates. A protonated ϵ nitrogen of H54, and a salt
83 concentration of 100mM NaCl were assumed for all studied systems, unless stated otherwise. In the simulated pilus, the
84 subunits were labeled from A (the most distant from the membrane) to R (the closest to the membrane) (**Figure 1B**). To reduce
85 the edge effects, we excluded from the analyses the 4 top (A-D) and 4 bottom (O-R) subunits and only considered the 10
86 intermediate protomers (E-N), hereafter designated as “bulk” subunits.

87 **Impact of pilin flexibility on length fluctuations**

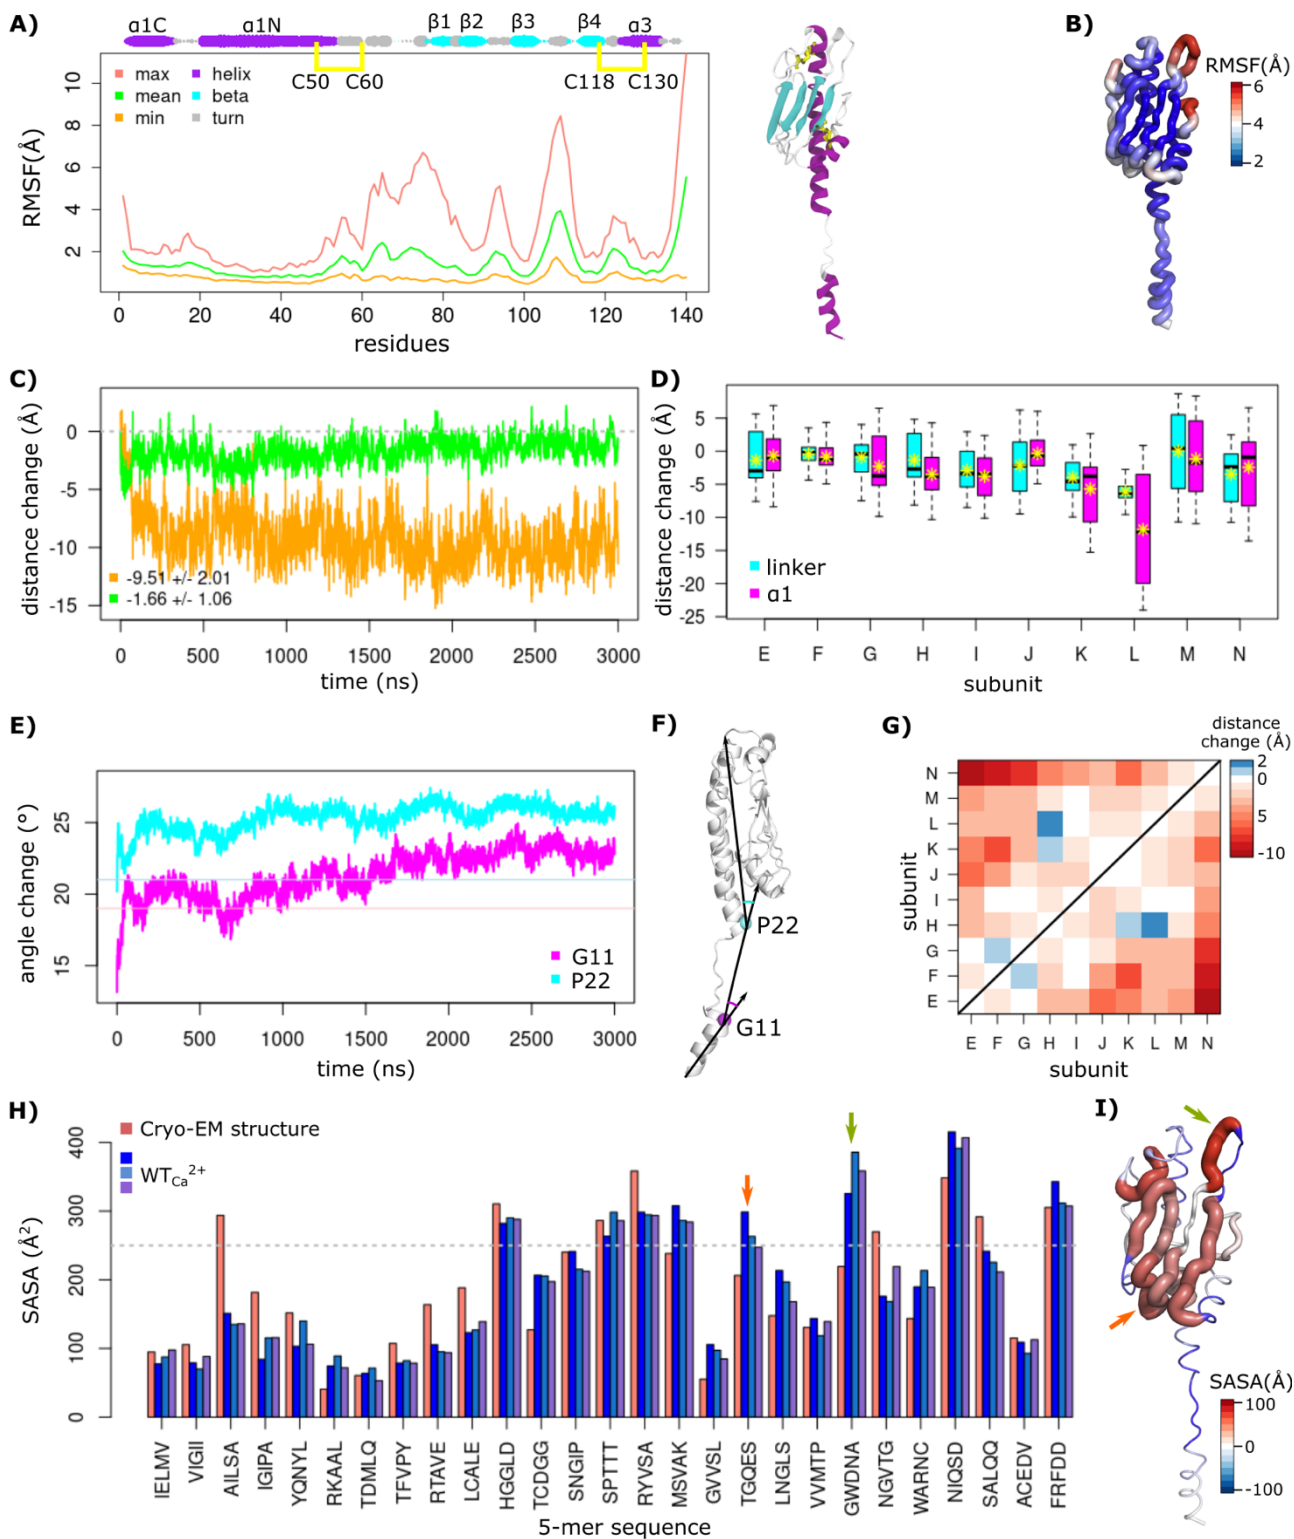

88 T4P are highly flexible fibers that undergo substantial length fluctuations (Biais et al. 2010) and show remarkable resistance
89 to force (Biais et al. 2008). We first studied in detail the relationship between individual residue fluctuations of EHEC pilin
90 subunits and the overall flexibility of the pilus bulk subunit in MD simulations of wild-type pilus in the presence of calcium
91 ($\text{WT}_{\text{Ca}^{2+}}$).

92 **Residue fluctuations.** The PpdD fold includes a long N-terminal α helix and a β -sheet globular domain (**Figure 1B**). The
93 middle of the N-terminal helix (residues G11 to P22) is unstructured in assembled pilins and is hereafter referred to as the
94 linker. Similar to most T4a pilins, a disulfide bond stabilizes the C-terminal loop (C118 - C130) of PpdD, in addition to a
95 disulfide bond between residues C50 and C60, conserved in the enterobacterial T4aP subclass (**Figure 1B**). The dynamics of
96 every region, calculated as the root mean square fluctuations (RMSF) of every residue with respect to the average conformation
97 during the final 2.5 μs from the three MD replicates, is shown in **Figure 2A**. The maximum fluctuations (RMSF_{max}) mapped
98 on the structure (**Figure 2B**) revealed several highly flexible regions ($\text{RMSF}_{\text{max}} > 4 \text{ \AA}$): *(i)* G62-V81 (α/β loop and $\beta 1$), *(ii)*
99 E92-N95 ($\beta 2/\beta 3$ loop), *(iii)* W105-T112 ($\beta 3/\beta 4$ loop), and *(iv)* D137-N140, the C-terminal region.

100 **Filament dynamics.** PpdD has the longest linker of any other pilus of this class, providing more flexibility to the filament
101 (Bardiaux et al. 2019). To further explore its role, we investigated how the $\alpha 1$ helix and filament length changes correlate with
102 the dynamics of the linker region. In principle, changes of filament length could be achieved by re-arrangements of the pilins
103 as more or less rigid blocks, or by conformational changes within the pilins. We found that, while the filament length changes
104 along the simulation were large, the changes of the bulk subunits were subtle, with an average length decrease of 1.7 \AA (**Figure**
105 **2C**). We calculated all changes of distance as the difference between the instantaneous values along the MD simulations and
106 the initial values in the cryo-EM structure. The changes of distance along the linker region and $\alpha 1$ (see **Methods**) in the three
107 replicates along every subunit show an overall reduction of length for both the linker and $\alpha 1$ (**Figure 2D**). We also measured
108 the angles formed at the two ends of the linker region: G11 and P22 (see **Methods** for angle definition), and observed an overall
109 increase along the simulations (**Figure 2E**), indicating bending of $\alpha 1N$ and $\alpha 1C$ (**Figure 2F**). Hence, the overall reduction of
110 the filament length in the simulations is predominantly a consequence of the high flexibility of the linker and an increase of
111 the angles formed between the two segments of $\alpha 1$ and the linker. The linker was the main region responsible for overall length
112 fluctuations of the filament, with a correlation coefficient of 0.8 (**Figure S1**). The overall reduction of length along the pilus
113 was accompanied by a decrease in the separation between globular domains of the bulk subunit (**Figure 2G** and **Figure S1**).
114 In T4aP, due to the helical symmetry, every subunit (S), makes contacts with six other subunits (S_{-4} , S_{-3} , S_{-1} , S_{+1} , S_{+3} , S_{+4}),
115 along the right-handed 1-start, left-handed 3-start and right-handed 4-start helices (Bardiaux et al. 2019). We observed a larger
116 reduction of the S distance to subunits S_{+3} and S_{+4} (**Figure 2G**). Consequently, the overall length reduction along the pilus long
117 axis brings pilin subunits closer to each other, resulting in compaction and strengthening their contacts.

118 **Exposed segments.** To understand how pilus dynamics modifies solvent exposure of different regions during MD simulations,
119 we divided the PpdD primary sequence into contiguous pentapeptide segments and compared their solvent accessibility
120 (SASA, \AA^2) to the starting cryo-EM structure (**Figure 2H**). We classified segments with a SASA of greater than 250 \AA^2 as
121 exposed. The results show that residues in the linker and $\alpha 1$ helix become more buried, while the residues of the globular
122 domain $\beta 1-\beta 4$ become more exposed. The differences between the average SASA from MD simulations and the initial values
123 from the cryo-EM structure were mapped on the pilin structure (**Figure 2I**). For two segments in particular $^{-89}\text{TGQES}^{93}$ and
124 $^{104}\text{GWDNA}^{108}$ – highlighted with red and green arrows, respectively, the average SASA increased strongly over the

125 simulations, indicating that the $\beta 2/\beta 3$ and $\beta 3/\beta 4$ loops (**Figure 2I**) become more exposed to the solvent. Interestingly, the
 126 $^{104}\text{GWDNA}^{108}$ peptide on the $\beta 3/\beta 4$ loop also showed the highest degree of fluctuations from the RMSF analysis (**Figure 2B**).
 127 Previous NMR studies identified the same region as highly dynamic in the PpdD monomer in solution (Bardiaux et al. 2019).

128

129 **Figure 2. Residue fluctuations of the wild-type T4P from the MD simulations.** (A) The per-residue RMSF of atomic coordinates are
 130 measured from the MD simulations, with respect to the average conformation. The maximum, minimum and average RMSF values were
 131 calculated over the bulk subunits from the three replicates and plotted as pink, orange, and green curves, respectively. The secondary
 132 structures are indicated (size of the rounds proportional to the persistence of the secondary structure along the MD trajectories). The starting
 133 structure of a single subunit is shown with the α helices and β strands colored in purple and cyan, respectively. The two disulfide bridges are

134 shown as yellow sticks. (B) The maximum RMSF values are mapped on the structure. (C) The average filament distance change is measured
135 over the three replicates for the full-length pilus (in orange), and bulk subunit (in green). (D) The changes of distances between the C α atoms
136 of the first and last residues of the linker (G11 and P22, in cyan), and α 1 (F1 and E53, in magenta) are reported for bulk subunit with respect
137 to their initial size, over the last 2.5 μ s of each replicate simulation. The average values for each subunit (letters E to N) are shown with
138 yellow stars. (E) The changes of angles formed at the G11 (in magenta), and P22 (in cyan) are averaged over bulk subunit and the replicates.
139 Their initial values from the cryo-EM structure are shown with horizontal lines. (F) The segments used for the calculations of angles in (E)
140 are shown on the structure. (G) Changes of distance between the center of mass of bulk subunit globular domains (β 1– β 4) are averaged over
141 the replicates. (H) The average SASA of 5-mers over the subunits of pilus are shown in shades of blue for the replicates, and pink for the
142 initial structure (PDB code: 6GV9). The gray line corresponds to the threshold used for the predictions of exposed regions. The arrows point
143 to the segments that become exposed. (I) The difference between average SASA from the MD and the initial structure is mapped on the
144 structure, with colors from blue (buried) to red (exposed). Arrows indicate the loops ⁸⁹TGQES⁹³ (orange) and ¹⁰⁴GWDNA¹⁰⁸ (green) that are
145 the most exposed to the solvent.

146 **Influence of Hydrogen-bonding network on filament formation**

147 The analysis of MD trajectories in terms of inter-subunit Hydrogen-bonds (H-bonds) and salt bridges revealed the network of
148 interactions between the subunits (**Figure 3**). To analyze H-bonds, we recorded the inter-subunit interactions present for more
149 than 50% of the simulation time in at least one replicate and that are observed between at least three pairs of subunits along
150 the pilus symmetry (**Figure S2**). Salt bridges were studied by measuring distances between the center of mass of oxygen atoms
151 from the acidic side chains and the center of mass of nitrogen atoms from the basic side chains, for all bulk subunits (see
152 **Methods**). The results were mapped on one set of subunits within the helical symmetry (S₋₄S₋₃S₊) (**Figure 4A**), where the
153 thickness of the lines indicates the number of subunits for which the interactions are present. We observed 4 distinct pairs of
154 H-bonds and salt bridges at the S-S₊₁ interface, 5 pairs at the S-S₊₃ interface, and 2 pairs at the S-S₊₄ interface. A strong network
155 of H-bonds is present along the 1-start helix, involving mostly the α 1 helix, whereas the majority of salt bridges are formed
156 along the 3-start helix. Two sets of residues were pivotal for those interactions: *i*) K30, D35, E53, H54, R135, E92, E131,
157 D132, involved in salt bridges, and *ii*) T2, L3, E5, L16, Y27, Q38, R74, N140, forming H-bonds. Some residues formed both
158 salt bridges and H-bonds, *e.g.*, D35-R135 and K30-E53. To experimentally validate the predicted importance of these
159 interactions for pilus stability, we generated alanine substitutions and performed piliation assays. In our assay conditions,
160 around 50% of total wild-type PpdD was assembled into pili on average (**Figure 4B**). In comparison, piliation was fully or
161 partially impaired for a large number of these variants including T2A, E5A, L16A, Y27A, K30A, D35A, E53A, H54A, and
162 R74A, supporting the role of these residues in assembly or stability of EHEC pili.

163 We also measured the distances between all pairs of residues forming inter-subunit hydrophobic contacts for at least 70% of
164 the simulation time (averaged over the helical symmetry) and recorded those within 3 Å (**Figure S3**). As expected, the majority
165 of such residues belong to the α 1 helix and form strong hydrophobic contacts.

166 Applying COMMA2 analysis (Karami et al. 2018) to the wild-type bulk subunit allowed us to identify a set of communication
167 blocks (CB_S^{path}) in the pilus (see **Methods**). The residues within a CB_S^{path} are linked by communication pathways built by
168 transitivity. A communication pathway is defined as a chain of residues displaying correlated motions and linked by stable
169 non-covalent interactions, hence representing an efficient route to transmit information through physical interactions. The
170 COMMA2 analysis revealed nine different CB_S^{path} (**Figure 4C**), the largest of which (in red) contains residues from all 10 bulk
171 subunits. To estimate the overall communication, we computed the number of pathways longer than 3 residues, and mapped
172 intra-subunit (in black) and inter-subunit pathways (in red) on the structure of the pilus (**Figure 4D**). We found that the α 1-
173 helices play an important role in communications both within and between the subunits. Only 1% of the pathways constitute
174 the inter-subunit communications (1547 pathways out of 202884), mainly involving the α 1 helix residues. These results
175 highlight the essential role of the α 1 helix in pilus stability and allowed us to trace the communication route across the pilus.

176

177 **Figure 3. Inter-subunit interaction network.** (A) The strength of H-bonds, computed as the percentage of conformations in which the H-
 178 bond is formed and the total number of H-Bonds formed along the pilus symmetry are reported for the calcium free and bound form pilus
 179 with different protonation states of His 54: HSE (ϵ), HSD (δ), and HSP (ϵ - δ). (B) The distances (Å) between pairs of residues forming salt
 180 bridges at the interface between subunits of the pilus are shown. The values above x-axis are the frequency of each salt bridge along the pilus
 181 symmetry. The left right arrows below each plot highlight the symmetry type of the interacting pairs. The data regarding the calcium bound
 182 (HSE, HSD, HSP) and free forms of the pilus are colored in orange, cyan, salmon and purple, respectively.

183

184 **Figure 4. Inter-subunit interactions of the pilus.** (A) Key residues involved in the interactions forming the pilus symmetry are highlighted
 185 on the first set of four protein subunits (S+1, S, S-3, S-4), colored in blue, green, pink and yellow, respectively. Dashed lines correspond to
 186 H-bonds and full lines to salt-bridges, where the thickness of the connections is proportional to their number of occurrences summed up
 187 according to the subunit symmetry along the pilus. (B) Dot plot comparing piliation efficiency of PpdD and its variants carrying alanine
 188 substitutions of individual residues. P values are shown above each graph as calculated in comparison with PpdD wild type piliation. (C)
 189 Pathways-based communication blocks (CBspath) identified by COMMA2 are mapped on the structure, with different colors. (D) The set
 190 of intra and inter-subunit pathways (> 3 residues) are displayed in black and red, respectively, as segments linking residues' C α atoms. The
 191 thickness of black segments is proportional to the number of pathways linking the residue pair.

192

Calcium binding by PpdD modulates the stability of T4P

193 Calcium is important for function and stability of some filaments of the T4P superfamily, including type II secretion pseudopili
 194 and archaeal flagella (Meshcheryakov et al. 2019; Lopez-Castilla et al. 2017; Korotkov et al. 2009). So far, however, its effect
 195 on T4aP has not been investigated. Solution NMR analysis indicated weak calcium binding to the soluble periplasmic domain
 196 of the PpdD pilin (residues 26–140) as shown by chemical shift perturbations (CSP) in the presence of EGTA (a calcium
 197 chelating agent) or calcium (**Figure 5A**). Addition of EGTA resulted in the highest CSP values for residues L28, A31,
 198 ⁵¹ALEH⁵⁴, F134 and F136. Among them, only E53 is negatively charged, located at the tip of the α 1 helix, in a loop defined
 199 by the disulfide bridge C50-C60. As calcium was not added to any of our buffers, this indicates that it was present in the protein
 200 sample purified from the bacterial periplasm. Upon addition of up to 40 mM calcium, we observed the highest CSP for the
 201 same region, notably for residues A31, E53, H54 and F136. Based on these results, we had placed one calcium ion close to

202 residue E53 in each PpdD subunit of the starting structure for the calcium-bound simulations (see **Methods**). Remarkably,
203 during the simulations, we observed a movement of calcium toward the interface of three subunits: S, S₊₃, and S₊₄. We explored
204 the interaction network in the vicinity of calcium, by comparing the calcium-bound and calcium-free simulations, and revealed
205 a set of residues surrounding the calcium: E53, H54 (in the S protomer), K30, E131, D132, R135, D137 (in S₊₃), and D35, E92
206 (in S₊₄) (**Figure 5BC**). Interestingly, this set of residues overlaps with the set crucial for the interactions between subunits
207 described above, forming H-bonds and salt bridges. Moreover, each calcium ion remained stable at the interface of three
208 subunits and resulted in the formation of stronger H-bonds and salt bridges (**Figure 3**). In the calcium-free simulations, residue
209 K30 (positively charged) interacts with residues E53 (negatively charged), through both H-bonds and salt bridges (**Figure 5B**).
210 However, the presence of calcium rearranged the interaction network due to its positive charge. In the calcium-bound
211 simulations we observed that calcium oscillates between E53 (negatively charged) and D132 (negatively charged) as shown in
212 **Figure 5C**. The distances between residues close to the calcium ion decreases overall by about 1 Å upon calcium binding, with
213 an average distance of 7 Å for the calcium-bound simulation (HSE), compared to 8 Å for the calcium-free one (**Figure 5D**).
214 While the distances decrease for most of the pairs, some exceptions are noted for K30-E53, R135-E53, and D132-H54. As
215 observed for the salt-bridges and H-bonds, this can be explained by the fact that calcium intercalates between these residues.
216 Although such rearrangements increase the distance between K30-E53 and R135-E53 and apparently weaken their contacts,
217 these interactions are actually reinforced through the presence of Ca²⁺ ion that bridges those residues and neutralizes their
218 charge. It is noteworthy that the side chain of H54 in its double protonation (HSP) state is closer to residue D137 (along the 3-
219 start symmetry) and to E92 (along the 4-start symmetry), further strengthening the network of interactions. Importantly,
220 functional assays show the importance of E53 and H54 residues for T4P assembly (**Figure 4B**).

221 MD simulation analyses suggest that calcium should stabilize the pilus. To test this prediction, we designed biochemical
222 experiments to assess the effects of calcium on pilus stability *in vitro*. Purified EHEC pili were incubated for 5 minutes at
223 increasing temperatures in the presence or absence of calcium. Upon ultracentrifugation, intact pili were recovered in the pellet
224 (P) and the dissociated subunits remained in the supernatant (S) (**Figure 5F**). The experiments showed that EHEC pili are quite
225 resistant to temperatures up to 60°C, but at 80°C they start to disassemble *in vitro*. Pili incubated with buffer alone or buffer
226 supplemented with EGTA behaved similarly, indicating a low level of divalent cation contamination in the buffer. Strikingly,
227 the addition of calcium stabilized the pili at 80°C, fully preventing dissociation of PpdD from the filaments. To better
228 characterize this effect, we carried out MD simulations at different temperatures (60°C and 80°C), in the absence and presence
229 of calcium. While the pilus remained stable at both temperatures of 60°C and 80°C, these conditions induced high global
230 fluctuations across the pilus (**Figure S4**), and secondary structure perturbations specifically around the α3 helix (**Figure S5**).
231 Higher fluctuations were detected in the area of C50-C60 loop at 80°C compared to 60°C, possibly correlating with loss of
232 fiber stability. However, for the simulations in the presence of calcium, we observed that the Ca²⁺ ions were not stable at their
233 initial binding region and moved away after 50-200 ns in each simulation.

234 We also investigated the effects of ions and salt concentrations by performing MD simulations of T4P in 100 mM salt
235 concentration by placing sodium (Na⁺), magnesium (Mg²⁺) or manganese (Mn²⁺) ions in the calcium binding site, or by
236 increasing the salt concentration to 150 mM in the presence of calcium (Ca²⁺). In the simulations with 100 mM salt, the
237 positively charged divalent ions behaved similarly to the calcium and remained stably bound in the same pocket, while in the
238 simulations with 150 mM, the Ca²⁺ ions moved away from the binding site.

239

240 **Figure 5. The effect of calcium binding on the overall interactions between subunits.** (A) Histogram showing the CSP values of PpdD
 241 backbone amide signals in the presence of calcium (8mM in dark blue and 40mM in cyan) and EGTA (5mM in orange), as a function of
 242 residue number. Residues displaying highest CSP (> 0.04 ppm) are labeled. (B) Residues displaying significant spectral changes in the
 243 presence of EGTA are labeled on the structure and colored according to their physico-chemical properties (hydrophobic in orange, positively
 244 charged in blue and negatively charged in red). (C,D) Key residues involved in the interactions between subunits and calcium are highlighted
 245 as sticks in different colors. The three subunits (S, S+3, S+4), are colored in pink, green and blue, respectively, while the rest of the pilus are
 246 in white. The calcium ion is shown as a yellow sphere. (E) The comparison of distance variations between pairs of residues in the
 247 neighborhood of the calcium, in the absence of the calcium (free), and presence of calcium (HSE, HSD, HSP). (F) Thermal stability of the
 248 EHEC T4P. Aliquots of isolated pili were incubated for 5 min at 20°, 40°, 60° and 80°C in 50 mM HEPES 50 mM NaCl buffer supplemented
 249 with either 10 mM EGTA, or 20 mM calcium. Total pili samples (T) were fractionated by ultracentrifugation (see **Methods**). Equivalent
 250 volumes of pellet (P) and supernatant (S) fractions were analyzed by denaturing electrophoresis on 10% Tris-Tricin polyacrylamide gels and
 251 stained with Coomassie blue.

252 **Histidine 54 and the importance of its protonation**

253 The single histidine (H54) at the tip of $\alpha 1$ helix, close to the calcium binding site is one of the key residues for the pilus
254 formation, conserved in the enterobacterial T4aP subclass (Luna Rico et al. 2019). Its mutation to alanine abolished piliation
255 (**Figure 4B**). To determine whether the protonation state of H54 affects pilus conformational stability, we performed three sets
256 of MD simulations at different pH around the pKa of H54: *i*) HSE (ϵ), *ii*) HSD (δ), and *iii*) HSP ($\epsilon-\delta$). First, we measured the
257 inter-subunit H-bonds over all the pairs of the bulk subunit, and recorded those that are present more than 50% of the simulation
258 time in at least one replicate and between 3 pairs of subunits (**Figure 3A**). This analysis suggests that both HSE and HSP
259 protonation states lead to stronger H-bond networks. However, the interactions are more persistent for HSE, occurring 38
260 times, compared to 34 for HSP. Interestingly, HSE results in the establishment of stronger H-bonds: (D35-R135) along the 1-
261 start, (L16-Q38 and K30-E53) along the 3-start and (T2-Y27) along the 4-start symmetry. Also, the number and persistence of
262 salt bridges are smaller for HSD (**Figure 3B**, the values above the x-axis). For both HSE and HSP, we observed salt bridges
263 starting from H54 along the 3-start and 4-start symmetry. This analysis revealed a direct impact of H54 protonation state on
264 stabilizing inter-subunit interactions, specifically along the 3-start and 4-start helical symmetry.

265 **The role of disulfide bridges and E5 on T4P structure and dynamics**

266 **Disulfide bridges.** The presence of two disulfide bridges is conserved in enterobacterial T4aP subclass. Disrupting either of
267 the two disulfide bridges led to a complete degradation of PpdD in bacteria, presumably due to increased exposure of dynamic
268 loop regions to proteolysis in bacterial periplasm (**Figure 6A**). To assess the dependence of pilus stability on disulfide bonds,
269 we treated purified pili with the reducing agent (DTT). Adding DTT had little effect on fiber stability at 60°C and below
270 (**Figure 6B**). At 80°C, however, pili were fully dissociated, emphasizing the importance of these disulfide bonds. To gain
271 molecular insight into their role, we performed MD simulations of pili lacking C50-C60 or C118-C130 disulfide bond. We
272 observed that for both mutants, calcium ions were not stable and the fluctuations around the average increased with respect to
273 the wild-type simulations, in particular close to the mutation sites (**Figure 6C**, the regions colored in red on the first two
274 structures from the left). Similar perturbations were also observed at the level of secondary structures around the strands $\beta 1$
275 for C50C60S Ca^{2+} , and $\beta 4$ for C118C130S Ca^{2+} (**Figure S5**). The mutations induced changes in interaction networks, with a
276 strong decrease in the number of salt bridges, their persistency, and increase in the distances for the two mutants (**Figure 6D**).
277 The only exception was the salt bridge between K30 and E53, which was more frequently present in the mutants compared to
278 the wild type. This can be explained by the fact that the Ca $^{2+}$ ions diffuse away in the simulations of mutants, allowing K30
279 and E53 to interact directly, compared to the wild-type simulations where this interaction was mediated by Ca $^{2+}$ ion.
280 Furthermore, the H-bond D35-R135 along the 1-start symmetry of the pilus became less stable, with the average strength of
281 0.59 for the wild type compared to 0.33 for the C50C60S Ca^{2+} , and 0.28 for the C118C130S Ca^{2+} (**Figure 6E**).

282 **Role of residue E5.** The Alanine substitution of residue E5 prevents PpdD assembly (Bardiaux et al. 2019) (**Figure 6A**). We
283 created the E5A variant *in silico* and carried out MD simulations in the absence and presence of calcium ions. For the
284 simulations in the presence of calcium, we observed that Ca $^{2+}$ ions were not stable, and moved away from their initial binding
285 pocket. The comparison of local residue fluctuations with those of the wild-type pilus showed that the E5A substitution induces
286 local perturbations around the fifth position (**Figure 6C**), as well as at the level of secondary structures in the $\alpha 1N$ region
287 (**Figure S5**). The mutation induced a major decrease in inter-subunit interaction strength and persistency (**Figure 6D,6E**). The
288 total number of H-bonds along the pilus was reduced by about 50% (21 and 20 for E5A and E5A Ca , respectively, compared to
289 38 for wild type). On the other hand, intra-subunit interactions between E5 and F1 were increased from 51% in the simulations
290 of the wild type to 82% and 74% in the E5A and E5A Ca simulations, respectively. This can be explained by the disruption of
291 the inter-subunit contacts of E5 along the 1-start helix.

292

293 **Figure 6. Role of disulfide bonds and E5 in pilus stability.** (A) Piliation assay with single and double mutant variants. (B) Thermal stability of the EHEC T4P in the presence (BUFFER) and absence (DTT) of disulfide bridges. Total pili samples (T) were fractionated by ultracentrifugation and equivalent volumes of pellet (P) and supernatant (S) fractions were analyzed (see Methods). (C) The differences between the average per-residue RMSF are measured from the MD simulations of the C50C60S_{Ca²⁺}, C118C130S_{Ca²⁺}, E5A (free form), and E5A_{Ca²⁺} (from left to right), with respect to the wild-type (HSE) pilus. The differences are then mapped on the structure of each system. The mutation positions are shown with yellow sticks and pointed to by black arrows. (D) The distances between pairs of residues forming salt bridges, and (E) strength and frequency of H-bonds at the interface between subunits of the mutants are reported. The values above x-axis are the frequency of each salt bridge. The left right arrows below each plot, highlight the symmetry type of the interacting pairs.

301

DISCUSSION

302 For this study of the conformational dynamics and stability of the EHEC T4P, we used a total of 108 μ s MD simulations of the wild-type T4P in different conditions, *i.e.*, in presence and absence of different ions, protonation states, and salt concentrations, as well as point mutations, validated by experimental studies. It enabled us to identify regions responsible for the flexibility of the pilus, playing key roles for the overall length fluctuation of the filament. Moreover, our simulations

306 revealed the network of interactions governing the communications across T4P, and allowed us to characterize a novel type of
307 a calcium binding site that specifically stabilizes the assembled pilus polymer.

308 This study is to the best of our knowledge the most extensive study of the conformational dynamics and stability of a filament
309 of this class. It is also the first study that uses a complete structural model with the “linker region” in the N-terminal helix. The
310 loss of helical structure in $\alpha 1$ N regions delimited by Gly and Pro residues was observed in the cryo-EM reconstructions of T4P
311 from *N. meningitidis* (Kolappan et al. 2016), *N. gonorrhoeae* (Wang et al. 2017), *P. aeruginosa* (Wang et al. 2017), and EHEC
312 (Bardiaux et al. 2019) in the 5-8 Å resolution range, in addition to two higher resolution structures for the wide and narrow
313 forms of *T. thermophilus* with the resolutions of 3.2 Å and 3.5 Å, respectively (Neuhaus et al. 2020), and the structure of the
314 homologous T2SS pseudopilus from *Klebsiella oxytoca* with a resolution of 5 Å (Lopez-Castilla et al., 2017). It has been
315 proposed that this conserved feature of T4P facilitates the integration of pilin subunits into the pilus (Kolappan et al. 2016),
316 allows T4P to withstand the extension under force, and to relax back to a native state when the force is removed (Wang et al.
317 2017). MD studies predating these structures, such as the atomistic and coarse-grain steered MD simulations to study the force-
318 induced conformational changes of a T4P from *Neisseria gonorrhoeae* (Zhao et al. 2017; Baker, Biais, and Tama 2013), were
319 based on structural models of T4P with a continuous N-terminal helix. It is interesting that in those steered MD simulations,
320 the pilus length variation was also linked to the particular region between G14 and P22 in the subunit. Among all the known
321 structures of pili, the EHEC T4P has the longest linker region in the $\alpha 1$ helix, extending from residues G11 to P22. Our analysis
322 identified in particular the role of the linker region in fiber flexibility: changes of its length show a strong correlation (0.8) with
323 the overall flexibility of the filament. Such high correlation could explain the role of the linker in the filament resistance under
324 force.

325 Despite the fact that in our simulations the pilus was in the “resting state” and absence of any forces, we observe an overall
326 reduction of length at different levels, in the linker, $\alpha 1$ helix, globular domains and consequently along the pilus. Residues in
327 the linker and $\alpha 1$ helix become more buried, while the residues of the globular domain $\beta 1$ – $\beta 4$ become more exposed. This is
328 consistent with the decrease of separation between the subunits, resulting in residues along the $\alpha 1$ helix becoming more buried.
329 The reason for the length reduction in our simulations could be that we only simulate a small fraction of the pilus. Forces are
330 typically generated by adding or removing pilin subunits, respectively, at the base of the pilus, leading to the extension or
331 retraction of the pilus. These extension-attachment-retraction cycles are powered by the strongest linear motors (ATPase)
332 known to date, and T4Ps have remarkable resistance to forces in the range of 100 pN (Clausen et al. 2009; Maier et al. 2002;
333 Merz, So, and Sheetz 2000). It was also shown that the reversible force-induced conformational changes revealed the exposure
334 of a hidden epitope (Biais et al. 2010), and the resistance to force was linked to the packing of $\alpha 1$ helices, maintaining their
335 hydrophobic contacts within the core of the pilus (Baker, Biais, and Tama 2013). The N-terminal half of the $\alpha 1$ helix is highly
336 conserved in the T4P, and is almost completely made up of hydrophobic residues, with the exception of T2 and E5. Our
337 simulations highlight the role of hydrophobic contacts between the $\alpha 1$ -helices in holding the core of the pilus together.
338 However, they also underline the essential role of polar residues forming H-bonds (T2, L3, E5, L16, Y27, Q38, R74, N140)
339 and salt bridges (K30, D35, E53, H54, R135, E92, E131, D132) at the interface of pilin subunits, along the 1-, 3-, and 4-start
340 helix. Our results are in agreement with previous charge inversion mutagenesis analysis, which showed that the majority of
341 charged EHEC T4P residues are required for pilus assembly (Bardiaux et al. 2019). At the same time, normal mode analysis
342 of EHEC T4P indicated the role of interactions along the 3-start helix in pilus rigidity (Bardiaux et al. 2019). Our study
343 highlights the crucial interplay of the linker region in $\alpha 1$, whose intrinsic flexibility induces long range dynamics along the
344 filament, while the hydrophobic and polar interactions between the tightly packed helices provide stability.

345 In bacterial cells disulfide bridges are essential for PpdD monomer stability and protease resistance precluding the detailed
346 analysis of their molecular role. MD data, coupled with the *in vitro* biochemical assays of an increase in temperature provided
347 a consistent picture of the role of the disulfide bridges in the stability of T4P.

348 Strictly conserved residue E5, is crucial for T4P assembly, since it contributes to integration of pilin subunits into the pilus
349 (Bardiaux et al. 2019; Nivaskumar et al. 2014; Lory and Strom 1997). The mutation E5A prevents the assembly at multiple
350 levels (Luna Rico et al. 2019), and probably pilin extraction from the membrane as suggested by studies of the effects of E5A
351 on the T2SS pseudopilin PulG (Santos-Moreno et al. 2017). Our MD data supports an additional role of this residue at the level
352 of inter-protomer interactions, mostly by stabilizing the interactions between T2 and L3 on one subunit and E5 on the adjacent
353 subunit, in agreement with previous work on other T4P (Craig et al. 2006; Wang et al. 2017).

354 MD simulations revealed the structural role of calcium in a member of the T4aP family, for which no classical calcium binding
355 site had been described. By combining NMR chemical shift perturbation analysis, biochemical assays and MD simulations we
356 revealed the molecular mechanism of calcium-mediated fiber stabilization. Simulations show how calcium bound at the tip of
357 the pilin monomer becomes coordinated in assembled pili by additional residues from subunits S₊₃ and S₊₄, acting as a
358 molecular glue. The set of residues involved in the interactions with calcium (K30, D35, E53, H54, E92, E131, D132, R135,
359 D137) largely overlaps with the set of residues involved in the network of H-bonds and salt bridges. We observed that
360 calcium remains stable at the interface between pilin subunits, and results in the formation of stronger salt bridges and H-bonds
361 at the interface. We also showed that the residues in the proximity of the calcium-binding region became more solvent exposed
362 during the simulations. Complementary functional assays confirmed a subset of the residues in the calcium-binding region as
363 critical for T4P assembly. In addition, *in vitro* biochemical assays showed that pili are resistant to temperatures up to 60°C and
364 they start to disassemble only at 80°C. These results confirm previous findings regarding the thermal stability of meningococcal
365 pili, also members of the T4aP subclass (Li, Egelman, and Craig 2012). Strikingly, the addition of calcium stabilized pili even
366 at 80°C, fully preventing the dissociation of PpdD from the assembled filaments. Even though the simulations were too short
367 to capture pilus dissociation, large fluctuations and secondary structure perturbations are in line with the biochemical data on
368 fiber stability. Simulations with different ions support the requirement of positively charged divalent ions for stable binding.

369 The importance of calcium and the identification of a metal binding pocket at the interface between pilins in the simulations
370 raises the possibility that this pocket could be exploited for drug discovery, since small molecules could bind there, affecting
371 T4P assembly or function. T4P are virulence factors in many human pathogens. Newly emerging anti-virulence strategies have
372 been developed to target the ATPases of T4P at the cytoplasmic base, resulting in disassembly of the pilus (Denis et al. 2019;
373 Duménil 2019). Targeting the pilus directly rather than the basal body would have the advantage that potential drugs do not
374 need to traverse the bacterial membrane.

375 This extensive characterization of the conformational landscape of T4P allowed us to reveal, at atomistic detail, the network
376 of dynamic interactions between subunits and the role of different regions in modulating the filament flexibility. Such
377 characterization of the conformational dynamics can also explain the physico-chemical basis of the molecular mechanisms
378 behind the fluctuations in the overall length of the pilus. This valuable information has a profound impact at multiple different
379 levels. From a fundamental point of view, our study elucidated the physico-chemical interactions that drive the behavior of
380 large and dynamic molecular assemblies. These interactions must provide an optimal balance between structural integrity of
381 the filaments and the flexibility required to perform their biological functions and to resist under stress. Furthermore, the
382 acquired knowledge will guide rational strategies to modulate the behavior of these filaments that are critical for a variety of
383 bacterial functions related to virulence.

384 **METHODS**

385 **PPDD CALCIUM BINDING MONITORED BY NMR**

386 The soluble periplasmic domain of EHEC PpdD comprising residues 26–140 of the mature protein, was produced and purified
387 as previously reported (Bardiaux et al. 2019; Amorim et al. 2014). NMR data were acquired at 293 K on a Varian spectrometer
388 operating at a proton frequency of 500 MHz. Proton chemical shifts were referenced to 2,2-dimethyl-2-silapentane-5 sulfonate
389 (DSS) as 0 ppm. ¹⁵N were referenced indirectly to DSS (Wishart et al. 1995). The pulse sequences were from VnmrJ Biopack.
390 NMR data were processed with NMRPipe/NMRDraw (Delaglio et al. 1995) and analyzed with the CcpNmr Analysis software
391 package (Vranken et al. 2005). ¹H–¹⁵N HSQC experiments were acquired on 0.4 mM PpdD in 50 mM Tris-HCl pH 7, 50 mM
392 NaCl supplemented with either EGTA at 5mM or CaCl₂ from 8-40 mM. Chemical shift perturbations (CSPs) of PpdDp
393 backbone amide cross-peaks were quantified by using the equation $CSP = [\Delta \delta H^2 + (\Delta \delta N \times 0.159)^2]^{1/2}$, where $\Delta \delta H$ and $\Delta \delta N$
394 are the observed ¹H and ¹⁵N chemical shift changes between the two experimental conditions. The residues belonging to the
395 tag were not considered for this analysis. The ¹H and ¹⁵N resonance assignments were from (Amorim et al. 2014).

396 **PILUS THERMAL STABILITY ASSAY**

397 The *E. coli* strain PAP5386 is a *fimAB::kan ΔfliC* derivative of BW25113 F'*lacI*^Q (Datsenko and Wanner 2000). Bacteria were
398 transformed with plasmids pMS41 encoding EHEC T4P assembly system and pCHAP8565 carrying the major pilin gene *ppdD*
399 (Luna Rico et al. 2019). Bacteria were cultured for 5 days at 30°C on solid M9 glycerol agar plates containing 100 μg.mL⁻¹ of
400 carbenicillin (Cb) and 25 μg.mL⁻¹ of chloramphenicol (Cm), supplemented with 1 mM isopropyl-β-D-1-thiogalactopyranoside

401 (IPTG) to induce the expression of the T4P genes. Bacteria were harvested and pili were extracted by shearing and concentrated
402 by ultracentrifugation as described previously (Luna-Rico, Thomassin, and Francetic 2018). To assess pilus stability, the
403 equivalent amounts of pili were taken and resuspended in buffer (50 mM HEPES, 50 mM NaCl). The pilus samples were
404 supplemented with 10 mM EGTA, 10 mM EGTA + 20 mM CaCl₂, or 40 mM DTT, incubated at indicated temperatures for 5
405 min and then placed on ice. Intact pili were separated from dissociated subunits by a 30-min centrifugation at 53 000 rpm in
406 the Beckman TLA55 rotor and table-top ultracentrifuge at 4°C. Equivalent amounts of total (T), pili-containing pellet (P) and
407 supernatant fractions containing dissociated pilin subunits (S) were analyzed on 10% Tris-Tricin SDS-PAGE and stained with
408 Coomassie blue.

409 **SITE-DIRECTED MUTAGENESIS**

410 Mutations were introduced into the *PpdD* gene carried on plasmid pCHAP8565 by a modification of the QuickChange method
411 for site-directed mutagenesis, as described previously (Bardiaux et al. 2019). The plasmids used in this study and mutagenic
412 oligonucleotide primers are listed in **Tables S1** and **S2**.

413 **PILUS ASSEMBLY ASSAYS**

414 To analyze pilus assembly, bacteria of *E. coli* strain BW25113 F'*lacI*^Q were transformed with plasmid pMS41 encoding the
415 EHEC pilus assembly genes and pCHAP8565 or its mutant derivatives encoding PpdD variants (Luna Rico et al. 2019).
416 Bacteria were cultured for 48-72 hours on M9 minimal agar plates (Miller 1972) containing Cb (100 µg.mL⁻¹) and Cm (25
417 µg.mL⁻¹). Bacteria were harvested and resuspended in LB medium at OD_{600nm} of 1. The suspension was vortexed vigorously
418 for 1 min to detach pili from bacteria. Bacteria were pelleted by 5-min centrifugation at 16000 g at 4°C and resuspended in
419 SDS sample buffer at a concentration of 10 OD_{600nm} per 1 mL. The supernatant containing pili was subjected to another round
420 of centrifugation for 10 min. Pili were precipitated with 10% tri-chloroacetic acid on ice for 30 min and pelleted by a 30-min
421 centrifugation at 16000g at 4°C. Pili pellets were washed twice with ice-cold acetone, air-dried and resuspended in SDS-sample
422 buffer at a concentration equivalent to that of the bacteria. The equivalent volumes of each fraction were analyzed by denaturing
423 SDS polyacrylamide gel electrophoresis (SDS-PAGE) on 10% polyacrylamide Tris-Tricine gels (Schägger and Von Jagow
424 1987). Proteins were transferred on nitrocellulose by Western blot and probed with anti-PpdD antibodies and secondary anti-
425 rabbit antibodies coupled to HRP as described (Luna Rico et al. 2019). The fluorescent signal was recorded with a Typhoon
426 FLA-9000 scanner (GE) and quantified by ImageJ. Data were processed and statistically analyzed with GraphPad Prism8
427 software.

428 **MOLECULAR DYNAMICS SIMULATIONS**

429 **Studied systems.** The 3D coordinates of EHEC T4P were retrieved from the Protein Data Bank (Berman et al. 2000) with
430 PDB code: 6gv9, residues 1 to 140, 8 Å resolution (Bardiaux et al. 2019). The published structure contains 14 subunits of the
431 major pilin PpdD; each subunit comprises (i) a long N-terminal helix ($\alpha 1$) that is broken into two helices ($\alpha 1N$ and $\alpha 1C$) by
432 an extended linker from G11 to P22, (ii) four β strands forming a β sheet ($\beta 1-\beta 2-\beta 3-\beta 4$), (iii) a long loop (α/β loop)
433 connecting the $\alpha 1$ to the β domain, and (iv) another helix ($\alpha 3$) at the C-terminus (**Figure 2A**). Two disulfide bonds are present
434 in each subunit, between Cys residues (C50, C60) and (C118, C130). We performed the MD simulations of T4P in a 1-
435 palmitoyl-2-oleoyl-sn-glycero-3-phosphoethanolamine (POPE) model membrane. The protein was initially placed near the
436 membrane with the linker and N-terminus of the first subunit partially inserted into the bilayer (**Figure 1B**). The number of
437 subunits was increased from 14 to 18 by applying the internal helical symmetry parameters. Moreover, the environment of the
438 histidine (H54) was manually checked, and consequently protonated with a hydrogen at the ϵ nitrogen. We also performed MD
439 simulations at two other protonation states: (i) a protonated δ nitrogen, and (ii) two protonated ϵ and δ nitrogens. In addition,
440 a single substitution (E5A) and two double substitutions (C50C60S and C118C130S) were studied *in silico* using the
441 CHARMM-GUI server (Jo et al. 2008).

442 **Ion placement protocol.** We identified the calcium binding site using NMR and by titration of T4P with calcium (see **PpdD**
443 **calcium binding monitored by NMR**). From this experiment four consecutive residues, ⁵¹ALEH⁵⁴ showed the highest
444 chemical shift perturbation, among which only E53 is negatively charged. Consequently, we placed the calcium ion (Ca²⁺)
445 close to this residue, and performed minimization. In addition to calcium, we evaluated the effect of other ions, namely: sodium
446 (Na⁺), magnesium (Mg²⁺) and manganese (Mn²⁺). These ions were placed at the same position than the one chosen for Ca²⁺

447 **Preparation.** All systems were prepared with CHARMM-GUI membrane builder server (<http://www.charmm-gui.org/?doc=1?4input/membrane>) and the CHARMM36m force field parameter set (Huang et al. 2017; MacKerell Jr, Feig, and Brooks
448 2004): (i) hydrogen atoms were added, (ii) the ions were positioned at the tip of $\alpha 1C$, following the procedure mentioned in
449 the previous paragraph, (iii) the POPE model membrane was used to build the inner bacterial membrane, (iv) the solute was
450 hydrated with a rectangular box of explicit TIP3P water molecules with a buffering distance up to 14 Å, (v) Na^+ and Cl^-
451 counter-ions were added to reproduce physiological salt concentration (100 mM and 150 mM solution of sodium chloride).
452 The following simulations were carried out: (i) T4P in the presence and absence of calcium with different protonation states:
453 WT , $WT_{\text{Ca}^{2+}}$, $WT^{(\delta)}_{\text{Ca}^{2+}}$, $WT^{(\varepsilon-\delta)}_{\text{Ca}^{2+}}$, (ii) T4P in the presence of different ions (calcium, sodium, magnesium, manganese) and
454 salt concentrations (100 and 150 mM): $WT^{\text{NaCl}150\text{mM}}_{\text{Ca}^{2+}}$, WT_{Na} , WT_{Mg} , WT_{Mn} , (iii) T4P in the presence and absence of calcium
455 at different temperatures (60°C and 80°C): WT^{60° , $WT^{60^\circ}_{\text{Ca}^{2+}}$, WT^{80° , $WT^{80^\circ}_{\text{Ca}^{2+}}$, and (iv) a set of single and double mutants of
456 T4P: $E5A_{\text{Ca}^{2+}}$, $C50C60S_{\text{Ca}^{2+}}$ and $C118C130S_{\text{Ca}^{2+}}$. A salt concentration of 100mM NaCl was used for all systems and the ε
457 nitrogen of H54 was protonated, unless stated otherwise. For each system, three replicates of simulations were performed.
458 Typically, these systems are composed of ~295,000 atoms, in a rectangular water box with dimensions of ~100 Å × 100 Å ×
459 308 Å. The details of all studied systems are reported in **Table I**.
460

461 **Table I. Details of the MD simulations.** All studied systems, as well as their corresponding temperature, number of replicates and simulation
462 time are reported here.

System	Name	Temperature (K)	# Replicates	Simulation length (ns)
Wild type	WT	310	3	3000
	$WT_{\text{Ca}^{2+}}$	310	3	3000
	$WT^{(\delta)*}_{\text{Ca}^{2+}}$	310	3	3000
	$WT^{(\varepsilon-\delta)}_{\text{Ca}^{2+}}$	310	3	3000
	$WT^{\text{NaCl-150mM}\#}_{\text{Ca}^{2+}}$	310	3	1000

463 *The protonation of ε nitrogen for H54.

464 #The salt concentration of 100mM NaCl were considered for all the studied systems, unless stated otherwise.

465 **Production of the trajectories.** The GROMACS 2019.4 package was used to carry out all simulations (Abraham et al. 2015).
466 The energy minimization was performed by steepest descent algorithm for 10000 steps, to minimize any steric overlap between
467 system components. This was followed by an equilibration simulation in an NPT ensemble at 310 K, allowing the lipid and
468 solvent components to relax around the restrained protein. All the protein and lipid non-hydrogen atoms were harmonically
469 restrained, with the constraints gradually reduced in 6 distinct steps with a total of 0.375 ns. The particle mesh Ewald algorithm
470 (PME) (Essmann et al. 1995) was applied to calculate electrostatic forces, and the van der Waals interactions were smoothly
471 switched off at 10-12 Å by a force-switching function (Steinbach and Brooks 1994). Production runs were performed in the

472 NPT ensemble. The time step was set to 2.0 fs, the temperature was kept at 310 K (except for the simulations at 333.15 K and
473 353.15 K), temperature was kept constant using the Nosé-Hoover thermostat (Melchionna, Ciccotti, and Lee Holian 1993) and
474 a constant pressure of 1 atm was maintained with the Parrinello-Rahman barostat (Parrinello and Rahman 1981). The SHAKE
475 algorithm (Kräutler, Van Gunsteren, and Hünenberger 2001) was used to freeze bonds involving hydrogen atoms, allowing for
476 an integration time step of 2.0 fs. The PME method (Darden, York, and Pedersen 1993) was employed to treat long-range
477 electrostatics. Half-harmonic potentials were applied at the tip of the pilus (subunit A-D), in order to prevent the dissociation
478 of the tip. PLUMED 2.6.0 (Tribello et al. 2014) and the PLUMED-ISDB (Bonomi and Camilloni 2017) module were used to
479 add lower and upper walls on the distance between the $C\alpha$ atoms of four pairs of residues ($T45_A-L52_B$, $T45_B-L52_C$, $T45_C-L52_D$,
480 $L49_D-K30_A$), with a force constant of 1000 kcal/(mol Å). The choice of residues was made according to their fluctuations, and
481 those with low deviations were selected. Coordinates of the system were written every 10ps. For every system, two or three
482 replicates were performed, starting with different initial velocities as reported in **Table 1**.

483 **Stability of the trajectories.** Standard analyses of the MD trajectories were performed with the *gmx* module of GROMACS
484 2019.4. All analyses performed in this study were applied to the “bulk” subunit, *i.e.* remaining 10 intermediate subunits, after
485 excluding 4 subunits from the top (A-D) and bottom (O-R) of the pilus (E-N). The root mean square deviations (RMSD) of
486 backbone atoms ($C\alpha$, C , N , O) from the initial frame were recorded along each replicate (**Figure S6**). Based on the RMSD
487 profiles, we performed the subsequent analysis over the subset of simulations where the systems are fully relaxed, *i.e.*
488 considering the last 900 ns, 1500 ns and 2500 ns for the simulations of 1000 ns, 2000 ns and 3000 ns, respectively. The per-
489 residue root mean square fluctuations (RMSF) were computed over the backbone atoms ($C\alpha$, C , N , O), with respect to the
490 average conformation (**Figure S6**). The secondary structures were assigned with DSSP (Kabsch and Sander 1983) and
491 averaged over the replicates (**Figure S5**). All studied systems remained stable along the MD trajectories.

492 **Stability of the trajectories.** Standard analyses of the MD trajectories were performed with the *gmx* module of GROMACS
493 2019.4. All analyses performed in this study were applied to the “bulk” subunit, *i.e.* remaining 10 intermediate subunits, after
494 excluding 4 subunits from the top (A-D) and bottom (O-R) of the pilus (E-N). The root mean square deviations (RMSD) of
495 backbone atoms ($C\alpha$, C , N , O) from the initial frame were recorded along each replicate (**Figure S6**). Based on the RMSD
496 profiles, we performed the subsequent analysis over the subset of simulations where the systems are fully relaxed, *i.e.*
497 considering the last 900 ns, 1500 ns and 2500 ns for the simulations of 1000 ns, 2000 ns and 3000 ns, respectively. The per-
498 residue root mean square fluctuations (RMSF) were computed over the backbone atoms ($C\alpha$, C , N , O), with respect to the
499 average conformation (**Figure S6**). The secondary structures were assigned with DSSP (Kabsch and Sander 1983) and
500 averaged over the replicates (**Figure S5**). All studied systems remained stable along the MD trajectories.

501 **Salt bridges:** We used VMD to detect salt bridges if the distance between any of the oxygen atoms of acidic residues and the
502 nitrogen atoms of basic residues are within the cut-off distance of 3.2 Å in at least one frame (Humphrey, Dalke, and Schulten
503 1996). Moreover, for every salt bridge we recorded the distance between the center of mass of the oxygen atoms from the
504 acidic side chains and the center of mass of the nitrogen atoms from the basic side chains. Then we merged the distances from
505 the three replicates of each system, and calculated the average distance of every pair.

506 **Hydrogen bonds:** We identified hydrogen-bonds (H-bonds) with the HBPLUS algorithm (McDonald and Thornton 1994). H-
507 bonds are detected between donor (D) and acceptor (A) atoms that satisfy the following geometric criteria: (i) maximum
508 distances of 3.9 Å for D-A and 2.5 Å for H-A, (ii) minimum value of 90° for D-H-A, H-AAA and D-A-AA angles, where AA
509 is the acceptor antecedent. For a given H-bond between residues i and j , an interaction strength is computed as the percentage
510 of conformations in which the H-Bond is formed between any atoms of the same pair of residues (i and j). We merged the
511 results from different replicates and assigned the maximum strength to every pair.

512 **Distances and lengths:** The length of the filament was measured as the distance between the center of mass of $C\alpha$ atoms of
513 residues A51-E53 in the first four subunits and the center of mass of $C\alpha$ atoms of residues F1-K30 in the last four subunits.
514 The length of the linker was defined as the distance between $C\alpha$ atoms of G11 and P22, and the length of the $\alpha 1$ helix as the
515 distance between $C\alpha$ atoms of F1 and E53. The separation between the globular domains were measured as the distance
516 between the center of mass of $C\alpha$ atoms from the residues forming the β sheet ($\beta 1$ – $\beta 4$) on each subunit. The changes of
517 distance were calculated as the difference between the observed values along the MD simulations and the initial values from
518 the cryo-EM structure.

519 **Angles:** We measured the angles at the two ends of the linker, *i.e.* G11 and P22. For that, we considered three segments over
520 the $\alpha 1$ helix: (i) residues F1-I10, (ii) I12-I21, and (iii) A23-E53, and measured the angles between them. The angle at G11 was
521 defined based on the lines that best fit to F1-I10 and I12-I21 segments. Similarly, the angle at P22 was calculated between the
522 lines that fit best to the I12-I21 and A23-E53 segments.

523 **Residue burial:** The average solvent accessible surface area (SASA, Å²) was measured for residues in the wild-type pilus with
524 the *gmx sasa* module of GROMACS for the initial cryo-EM structure and over the replicates of MD simulations. We identified
525 segments of 5-residue long (5-mer) and calculated the SASA of every 5-mer as the sum of corresponding residual SASA
526 values.

527 COMMA ANALYSIS

528 COMMA2 (Karami et al. 2018) was applied to the replicates of MD simulations, and communication blocks were extracted.
529 COMMA2 identifies pathway-based communication blocks (CBs^{path}), *i.e.* groups of residues that move together, and are linked
530 by non-covalent interactions, and clique-based communication blocks (CBs^{clique}), *i.e.* groups of residues close in space that
531 display high concerted atomic fluctuations. *Communication pathways* and *independent cliques* are used to construct a colored
532 graph $PCN(N, E)$ defined by nodes N that correspond to the residues of the protein and edges E that connect residues adjacent
533 in a pathway or belonging to the same clique. COMMA2 extracts connected components from the graph by using depth-first
534 search (DFS) to identify the protein *dynamical units*. These units are referred to as “communication blocks” (see (Karami,
535 Laine, and Carbone 2016) for formal definitions and detailed descriptions). *Communication pathways* are chains of residues
536 that are not adjacent in the sequence, form stable non-covalent interactions (hydrogen-bonds or hydrophobic contacts), and
537 communicate efficiently. *Communication efficiency or propensity* is expressed as (Karami, Laine, and Carbone 2016):

$$538 \quad CP(i, j) = \langle (d_{ij} - \bar{d}_{ij})^2 \rangle \quad (1)$$

539 where d_{ij} is the distance between the $C\alpha$ atoms of residues i and j and \bar{d}_{ij} is the mean value computed over the set of
540 conformations. Two residues i and j are considered to communicate efficiently if $CP(i, j)$ is below a *communication propensity*
541 *threshold*, CP_{cut} . The strategy employed to set the value of CP_{cut} is explained in (Karami, Laine, and Carbone 2016). However,
542 the algorithm is modified in this work by considering the definition of chains. Intuitively, it is expected that neighboring
543 residues in the sequence forming well-defined secondary structure, communicate efficiently with each other. Therefore, we
544 evaluate the proportion p_{ss} of residues that are in an α -helix, a β -sheet or a turn in more than half of the conformations. Then
545 for every residue i surrounded by 8 sequence neighbors (4 before and 4 after), we compute a *modified communication*
546 *propensity* $MCP(i)$ as:

$$547 \quad MCP(i) = \frac{1}{8} \sum_{\substack{j=i-4 \\ j \neq i; 1 \leq j \leq N; 5 \leq i \leq (N-4)}}^{i+4} CP(i, j) \quad (2)$$

548 where N is the total number of residues in each chain. CP_{cut} is chosen such that the proportion p_{ss} of MCP values are lower than
549 CP_{cut} . Whenever more than one replicate of MD trajectories is available, we measured the CP_{cut} for each replicate and
550 considered the average value for the identification of pathways.

551 COMPUTATIONAL TOOLS

552 Trajectories generated by MD simulations were analyzed with *gmx rms*, *gmx rmsf*, *gmx sasa* utilities of GROMACS 2019.4
553 (Abraham et al. 2015). VMD (Humphrey, Dalke, and Schulten 1996) and PyMOL (DeLano 2002) were used for visualization
554 and plots were generated using the R software package (Team 2013), and python (Van Rossum and Drake Jr 1995).

555 LEAD CONTACT

556 Further information and requests for resources should be directed to and will be fulfilled by the Lead Contact, Michael Nilges
557 (Michael.Nilges@pasteur.fr).

558 DATA AVAILABILITY

559 Raw MD trajectories and data are available from the authors upon request.

560 ACKNOWLEDGMENTS

561 This work was funded by the Institut Pasteur, the Centre National de la Recherche Scientifique, the Fondation pour la
562 Recherche Medicale (Equipe FRM 2017M.DEQ20170839114 to YK, ACL, NIP and MN), the French Agence Nationale de la
563 Recherche (grant ANR-19-CE11-0020 to OF, NIP and MN), the Institut Pasteur Roux- Cantarini fellowship and NSERC grant
564 (to JLT), Fulbright fellowship (to AO). YK would like to acknowledge the PRACE for awarding access to Piz Daint at CSCS,
565 Switzerland.

566 AUTHOR CONTRIBUTIONS

567 YK, NIP, OF and MN conceived the study. YK performed MD simulations and analyzed the data with BB, TM, NIP, OF and
568 MN. ALC and NIP performed NMR analysis. OF, JLT and AO analyzed pilus assembly and stability. YK, NIP, OF and MN
569 wrote the paper. All authors read and approved the manuscript.

570 DECLARATION OF INTEREST

571 The authors declare no competing interests.
