Abstract

Human excitatory amino acid transporters (EAATs) maintain glutamate gradients in the brain essential to neurotransmission and to prevent neuronal death. They use ionic gradients as energy source, and co-transport transmitter into the cytoplasm with Na^+ and H^+, while counter-transport K^+ to re-initiate the transport cycle. However, the molecular mechanisms underlying ion-coupled transport remain incompletely understood. Here, we present 3D structures and thermodynamic analysis of EAAT1 in different ion-bound conformations, including elusive counter-transport ion bound states. Binding energies of Na^+ and H^+, and unexpectedly Ca^{2+}, are coupled to neurotransmitter binding. Ca^{2+} competes for a conserved Na^+ site suggesting a regulatory role of Ca^{2+} in glutamate transport at the synapse, while H^+ binds to a conserved glutamate residue stabilizing substrate occlusion. The counter-transported ion binding site overlaps with that of glutamate, revealing the K^+ mechanism to exclude the transmitter during the transport cycle, and to prevent its neurotoxic release on the extracellular side.

Keywords: cryo-EM/Neurotransmitter transport/ permeation and transport/solute carrier/X-ray crystallography

Human excitatory amino acid transporters (EAATs) belong to the solute carrier 1 (SLC1) family, and catalyze active transport of excitatory transmitters using energy stored in ionic transmembrane gradients (Erecinska *et al*, 1983; Kanner & Sharon, 1978; Nelson *et al*, 1983). In each transport cycle, EAATs stoichiometrically co-transport one molecule of transmitter with 3 Na^+ and 1 H^+, while counter-transport 1 K^+ to re-orient the transmitter binding site to the extracellular side, and re-initiate the cycle (Barbour *et al*, 1988; Zerangue & Kavanaugh, 1996). EAAT1-2 are highly expressed on the plasma membrane of astrocytic glia (Lehre & Danbolt, 1998), where they are essential components of tripartite synapses and contribute to clear the transmitter from the cleft, as well as to regulate extracellular glutamate concentration in the brain (Zhou & Danbolt, 2014). Consistently, their dysfunctions are linked to several neurodegenerative disorders (Pajarillo *et al*, 2019).

SLC1 proteins are homo-trimers (Canul-Tec *et al*, 2017; Garaeva *et al*, 2018; Yernool *et al*, 2003; Yernool *et al*, 2004), and their individual subunits catalyze transport independently (Grewer *et al*, 2005; Koch & Larsson, 2005; Leary *et al*, 2007; Ruan *et al*, 2017). Each subunit contains two structural and functional domains (Reyes *et al*, 2009): a relatively rigid (Groeneveld & Slotboom, 2007) scaffold domain (scaD) that forms the inter-subunit interfaces; and a highly dynamic (Akyuz *et al*, 2013; Erkens *et al*, 2013; Matin *et al*, 2020) transport domain (tranD) that binds substrate as well as thermodynamically-coupled ions (Boudker *et al*, 2007; Guskov *et al*, 2016; Larsson *et al*, 2010; Seal & Amara, 1998; Tao *et al*, 2010; Zhang *et al*, 1998), and shuttles across the membrane in an “elevator-like” manner to translocate the cargo (Crisman *et al*, 2009; Reyes *et al.*, 2009).

Biophysical analyses of Na^+-dependent EAAT archaeal homologs, Glt_{Ph} (Boudker *et al.*, 2007) and Glt_{TK} (Guskov *et al.*, 2016), showed that co-transported sodium ions bind

three conserved sites in the tranD (Na1-3), and that binding energy of the three co-transported Na^+ ions is coupled to substrate binding and occlusion, rather than directly driving its translocation (Reyes *et al*, 2013). In the absence of substrate, two Na^+ bind cooperatively to Na1 and Na3, and contribute to form the substrate binding site, while subsequent binding of substrate and Na^+ to Na2 lead to substrate occlusion under helical-hairpin 2 (HP2) (Alleva *et al*, 2020; Ewers *et al*, 2013; Guskov *et al.*, 2016; Reyes *et al.*, 2013; Verdon *et al*, 2014). HP2 dynamics controls substrate access to its binding site on opposite sides of the membrane, and HP2 closure enables elevator-like movements of the tranD, and isomerization between outward- and inward-facing states (Alleva *et al.*, 2020; Boudker *et al.*, 2007; Garaeva *et al*, 2019; Reyes *et al.*, 2009). However, archaeal homologs are limited molecular models, as they are H^+ and K^+ independent transporters (Ryan *et al*, 2009). Moreover, archaeal Na^+-coupling mechanism has not been confirmed experimentally in EAATs. In addition, the folding instability of purified mammalian EAAT orthologs has precluded so far similar crystallographic and thermodynamic analyses of human transporters, and recent cryo-electron microscopy (cryo-EM) structures of EAAT3 fell short of revealing the complete ion-coupled mechanism (Qiu *et al*, 2021).

In this work, we set out to study EAAT ion-coupled transport mechanism using thermostabilized human EAAT1 mutants, namely $EAAT1_{CRYST}$ and $EAAT1_{CRYST\text{-}II}$ (Canul-Tec *et al.*, 2017; Cirri *et al*, 2018), as well as wild type EAAT1 ($EAAT1_{WT}$). $EAAT1_{CRYST}$ constructs are nearly identical to $EAAT1_{WT}$ at the core of the tranD, where transmitter and coupled-ions bind. Consistently, they retain intact Na^+, H^+, and K^+ coupled transport mechanism after purification in detergent solutions and reconstitution in synthetic liposomes. Importantly, detergent-purified $EAAT1_{CRYST}$ proteins are stable under different substrate and ionic conditions, and enable both

thermodynamic and X-ray crystallographic analysis of the neurotransmitter transport cycle, while $EAAT1_{WT}$ was amenable to structural analysis by cryo-EM.

Conserved SLC1 sodium-coupling mechanism

L-glutamate uptake by purified $EAAT1_{CRYST}$ is strictly dependent on opposite transmembrane gradients of sodium and potassium (Canul-Tec *et al.*, 2017). To quantify binding and ion-substrate thermodynamic coupling, we measured changes in intrinsic tryptophan fluorescence of purified $EAAT1_{CRYST}$ in detergent solutions. Both Na^+ and transmitter binding, but not K^+, induced robust tryptophan-fluorescence changes (> 15%) that enable titration of ligands (Fig. 1A,B). $EAAT1_{CRYST}$ contains two tryptophan residues, $W287_{267}$ in the scaD, and $W473_{453}$ in the tranD (herein, amino acid number refers to $EAAT1_{WT}$ sequence, and the corresponding number in $EAAT1_{CRYST}$ is in subscript). Individual phenylalanine mutants $W287_{267}F$ and $W473_{453}F$ decreased (~ 5%), and abolished, respectively, Na^+/transmitter induced fluorescence signal (Appendix Figure S1A). Although the structural details underlying tryptophan fluorescence changes in $EAAT1_{CRYST}$ are unclear, these experiments show that the two tryptophan residues are required to probe Na^+ binding, and that changes in tranD dynamics induced by Na^+ and K^+ binding are significantly different.

In the absence of substrate, sodium ions bind $EAAT1_{CRYST}$ in a cooperative manner with an apparent dissociation constant (K_D) of 21.6 ± 0.4 mM, and a hill coefficient (n_H) of 2.2 ± 0.1 (Fig. 1C), consistent with binding of two sodium ions to the apo tranD at Na1 and Na3. In agreement with this, asparagine mutation of strictly conserved $D400_{380}$ in Na3 greatly impaired sodium binding (K_D >100 mM). Moreover, in the presence of allosteric inhibitor $UCPH_{101}$ (Jensen *et al*, 2009), which traps the transporters in outward-facing states (Canul-Tec *et al.*, 2017), Na^+ titrations of $EAAT1_{CRYST}$ yielded similar binding parameters (K_D = 14.6 ± 0.3 mM; n_H = 1.6 ± 0.1).

111 These results indicate that tryptophan-fluorescence changes report on conformational
112 changes associated to binding, rather than membrane translocation of the tranD, and
113 further that Na^+ binds outward- and inward facing states with comparable affinities.
114 Substrate binding to $EAAT1_{CRYST}$ was strongly sodium-dependent, and the logarithmic
115 plot of the substrate K_D versus sodium concentration yielded a straight line with a slope,
116 or coupling efficiency (C_E) value of -2.6 ± 0.3 (Fig. 1D). C_E is the apparent number of
117 ions thermodynamically coupled to binding of one substrate molecule, and our results
118 show that in $EAAT1_{CRYST}$ the binding energy of the three co-transported sodium ions
119 is coupled to neurotransmitter binding. Moreover, at 1 mM Na^+, transmitter K_D values
120 in the presence (0.9 ± 0.1 mM) and absence of $UCPH_{101}$ (2.8 ± 0.8 mM) were
121 comparable.
122 Indeed, similarities in Na^+, and Na^+-transmitter coupled binding properties between
123 archaeal homologs (Reyes *et al.*, 2013) and $EAAT1_{CRYST}$ strongly suggests
124 conservation of the Na^+-coupling mechanism.
125 To gain structural insight on the location of the sodium binding sites, we extended the
126 reported crystallographic atomic model of Na^+/transmitter bound $EAAT1_{CRYST}$ (Canul-
127 Tec *et al.*, 2017) in complex with $UCPH_{101}$ (see methods). Notably, the extended model
128 includes an N-terminal helix that lies nearly parallel to the membrane plane (TM1a'),
129 and has not been noted before in structures of SLC1 proteins (Fig. 2A,B). Interes.tingly,
130 amino acid deletions in this region slow down substrate uptake by $EAAT1_{WT}$ expressed
131 in cells (Appendix Figure S1B), suggesting a modulatory role of TM1a' on transport
132 kinetics. Notably, $EAAT1_{CRYST}$ Fo-Fc electron density map omitting sodium ions
133 shows three distinct density peaks (> 4σ) within the tranD (Fig. 2C). Several lines of
134 structural and functional evidence indicate that the observed peaks correspond to three
135 co-transported Na^+ bound to the tranD: the peaks accurately localize to the three

conserved sodium binding sites (Na1-Na3) previously observed in X-ray structures of archaeal homologs (Alleva *et al.*, 2020; Boudker *et al.*, 2007; Guskov *et al.*, 2016). Accordingly, three sodium ions modeled in $EAAT1_{CRYST}$ structure reveal nearly identical coordination compared to the homologs (Fig. 2D); ion coordination in $EAAT1_{CRYST}$ at the three sites is exclusively done by oxygen atoms, as expected for a weak acid like Na^+, while water coordination is expected to have additional contributions by nitrogen atoms, reflecting its H-bonding capacity (Nayal & Di Cera, 1996); Finally, reported mutagenesis of residues that contribute side chains to Na1 and Na3, including $D400_{380}N$ (Fig. 1C), impaired Na^+-dependent function in both EAATs and prokaryotic homologs (Bastug *et al*, 2012; Boudker *et al.*, 2007; Tao *et al.*, 2010). Overall, the above structural and thermodynamic results are in excellent agreement with the sodium-coupling mechanism of archaeal transporters (Alleva *et al.*, 2020; Ewers *et al.*, 2013; Guskov *et al.*, 2016; Reyes *et al.*, 2013; Verdon *et al.*, 2014), and confirm its conservation in human SLC1 proteins. In this mechanism, cooperative Na^+ binding to apo transporters leads to occupancy of Na1 and Na3 sites and contributes to the formation of the substrate binding site, while subsequent binding of substrate and Na^+ to Na2 lead to substrate occlusion under HP2, and enables transmembrane movements of the tranD. Na^+, as well as Na^+-transmitter coupled binding affinities to outward- and inward-facing states are similar.

Proton coupling

L-glutamate uptake by purified $EAAT1_{CRYST}$ decreases steeply at basic pH values (Fig. 3A), resembling transport pH-dependence observed in EAAT mammalian orthologs expressed in cells (Watzke *et al*, 2000; Zerangue & Kavanaugh, 1996), and demonstrating that the proton-coupled transport mechanism of the thermostable mutant is intact.

To gain thermodynamic insight on this mechanism, we measured Na^+, as well as Na^+/transmitter coupled binding to apo transporters as a function of pH using the tryptophan-fluorescence assay. There was no significant change in Na^+ apparent K_D in a pH range from 6 to 10 ($C_E = 0.09 \pm 0.03$), while substrate K_D significantly increased with pH ($C_E=0.55 \pm 0.02$) at constant [Na^+] (Fig. 3B). These results demonstrate that neurotransmitter binding is thermodynamically coupled to binding of one H^+, and argue that cooperative Na^+ binding to apo transporters, at Na1 and Na3, is H^+-uncoupled. We next asked if the apo transporters are able to bind protons. Indeed, total tryptophan-fluorescence changes associated to saturating Na^+/transmitter coupled binding significantly decreased at pH values below neutral (Fig. EV1A,B), indicating that protons change tryptophan-fluorescence of apo transporter upon binding.

To find ionizable side chains that could act as proton acceptors in the tranD, we compared amino acid sequences from representative vertebrate species of two divergent branches of SLC1 transporters (Gesemann *et al*, 2010): pH-dependent EAATs, and pH-independent neutral amino acid exchangers (so-called ASCTs) (Fig. EV1C,D). The tranD of $EAAT1_{CRYST}$ contains over 30 ionizable side chains, but only $Y127_{127}$ (TM3), $Y405_{385}$ (TM7b), $E406_{386}$ (TM7b), and $R479_{459}$ (TM8b) are strictly conserved among EAAT orthologs, and not among ASCT ones. $R479_{459}$ is in close proximity to conserved acidic residues ($E406_{386}$, $D472_{452}$, and $D476_{456}$), while $Y127_{127}$ backbone is part of Na3, where Na^+ arguably binds in a pH-independent fashion. Hence, it is highly unlikely that those two residues exchange protons with the bulk during the transport cycle, and we focused our analysis on $Y405_{385}$ and $E406_{386}$. Indeed, conservative single mutations bearing non-ionizable sidechains had minor effects on pH-dependence of substrate binding in $Y405_{385}F$ ($C_E=0.37 \pm 0.06$), but abolished this dependence in $E406_{386}Q$ ($C_E=0.00 \pm 0.04$) (Fig. 3C). Our results agree well with early studies of rodent

ortholog EAAC1 showing that equivalent mutation to $E406_{386}Q$ (E373Q) impairs pH-dependence of apparent glutamate-binding (Grewer *et al*, 2003), as well as with molecular dynamic simulations of transmitter binding (Heinzelmann & Kuyucak, 2014), and support the role of E406 carboxylate as the main proton acceptor in the transport cycle.

From a structural viewpoint, $E406_{386}$ sidechain is occluded within the tranD core at hydrogen-bond distance of $G447_{427}$ backbone-carbonyl oxygen, $T450_{430}$ sidechain hydroxyl, and $M451_{431}$ backbone amide in HP2b in the Na^+/transmitter-bound $EAAT1_{CRYST}$ structure (Fig. 3D). Consistent with its proton acceptor role, protonation of $E406_{386}$ carboxylate group would expand its H-bonding capacity and enable formation of a H-bond network with HP2b, contributing to maintain HP2 in a close position with substrate occluded underneath, and explaining at least partly the thermodynamic coupling between H^+ and transmitter binding. Because it is not possible to determine the protonation state of amino acid sidechains in the $EAAT1_{CRYST}$ crystal structure, we determined the structure of $EAAT1_{CRYST}$-$E406_{386}Q$ mutant, mimicking the protonated state of $E406_{386}$. Indeed, the position of $E406_{386}Q$ side chain is identical within experimental error to that of $E406_{386}$ (Appendix Figure S2A,B), consistent with $E406_{386}$ being protonated in the Na^+/transmitter-bound state.

All functional and structural results converge to show that Na^+/transmitter bound structure represents the transmitter translocation complex of the tranD with 3 Na^+, 1 H^+, and 1 neurotransmitter molecule bound.

Counter-transported ion binding-site

To understand the structural basis underlying ion counter-transport in EAATs, we solved the crystal structure of transporters purified in Rb^+-based buffer, in the absence of Na^+ and transmitter, and in complex with $UCPH_{101}$. Rb^+ is a K^+ analog, and the

advantage for crystallographic experiments is that Rb^+ yields robust anomalous X-ray scattering signals to unambiguously determine the position of bound ion(s) to the transporter, at the resolution of our structure (~3.9 Å). Importantly, liposome uptake experiments show that Rb^+ is counter-transported by $EAAT1_{CRYST}$, demonstrating that it is a functional K^+ analog for EAAT1 structural studies (Fig. 4A).

Rb^+ and $UCPH_{101}$ bound $EAAT1_{CRYST}$ structure adopts an outward-facing open state, and the anomalous difference map with the X-ray beam tuned at a Rb^+ absorption maximum (0.815 Å) shows two anomalous-difference peaks (> 5σ), namely P1 and P2. P1 localizes to the substrate binding site near conserved $D476_{456}$, and P2 to Na3 (Fig. 4B). As negative control, we collected diffraction data from a similar crystal, but with the X-ray beam tuned off the Rb^+-absorption maximum (0.998 Å), and observed P2 (> 5σ), but not P1 in the anomalous-difference map (Fig. EV2). These results demonstrate that Rb^+, a functional counter-transported ion by EAAT1, is bound to the transporter at the substrate binding site. Notably, this counter-transported ion binding site, namely K_{CT}, overlaps with the position of the substrate amide-nitrogen atom in the Na^+/transmitter-bound structure, and it is coordinated by the carboxylate side chain of $D476_{456}$ (TM8b), backbone carbonyl oxygen of $S363_{343}$ (HP1), and possibly its sidechain, as well as that of $T480_{460}$ (TM8b) and water molecules (Fig. 4B). The striking overlap with the transmitter binding site makes K_{CT} an optimal site for the counter-transported ion to exclude the transmitter during the transport cycle. Consistently, early computational (Holley & Kavanaugh, 2009), functional (Wang *et al*, 2013) and crystallographic (Verdon *et al.*, 2014) studies of EAAT homologs predicted mutually exclusive transmitter and K^+ binding sites at similar positions.

Calcium binding to Na3 site

Our anomalous scattering analysis reveals a second ion bound to Na3 in the Rb^+ bound $EAAT1_{CRYST}$ structure. In addition to Rb^+ (at ~100 mM), crystallization conditions contain Ba^{2+} and Ca^{2+} (at ~25 mM), and only the former could generate significant anomalous peaks off the Rb^+ absorption maximum (0.998 Å). To shed light on this problem, we solved the structure of transporters purified in the absence of substrate, Na^+, and Rb^+, and using choline as a substitute for monovalent cations, but otherwise under similar crystallization conditions containing Ba^{2+} and Ca^{2+}. In these crystals, we found a single anomalous-difference peak that corresponds to P2 (> 8σ) at Na3 (Fig. 5A), consistent with Ba^{2+} binding at this sodium site. From a structural point of view, Ba^{2+} binding to Na3 would be possible through conformational changes around the ^{398}NMDG motif, particularly at the level of $N398_{378}$ that moves away from the center of the site compared to the transmitter bound structure, enabling occupancy by a larger cation than Na^+ (Fig. EV3).

From a functional perspective, Ba^{2+} binding to a conserved Na^+-binding site in EAATs raises the interesting possibility that physiologically-relevant analog Ca^{2+} would also bind there. Ca^{2+} and Ba^{2+} binding to $EAAT1_{CRYST}$ transporters was confirmed by changes in intrinsic-tryptophan fluorescence, and showed several important features: Ca^{2+} binds apo transporters with $K_D = 2.9 \pm 0.4$ mM in a non-cooperative manner ($n_H = 0.9 \pm 0.1$), and mutation $D400_{380}N$ increased its K_D by at least an order of magnitude (Fig. 5B), consistent with binding of one calcium ion to Na3; Ca^{2+} binding parameters were not significantly affected by allosteric inhibitor $UCPH_{101}$ ($K_D = 1.4 \pm 0.1$ mM; $n_H = 0.9 \pm 0.03$), implying that Ca^{2+} affinities to outward- and inward-facing states are comparable; Ca^{2+} (and Ba^{2+}), but not K^+ significantly increased Na^+ apparent K_D (Fig. EV4), indicating competitive binding between Ca^{2+} (or Ba^{2+}) and Na^+, as well as lack of K^+ affinity for Na1 and Na3; binding of substrate was thermodynamically coupled

to one Ca^{2+} (C_E = -0.8 ± 0.1) (Fig. 5C), as expected for a cation that binds to Na3. In addition, reconstituted transmitter uptake in liposomes demonstrates that Ca^{2+} is not counter-transported (Fig. 4A), at least not at rates comparable to K^+ or Rb^+, suggesting that a cation bound to Na3 is not able to form a translocation complex to re-locate the substrate binding site. However, Ca^{2+} weakly inhibited transport with half-maximal inhibitory concentrations (IC_{50}) ~5 mM, when added to K^+-containing intra-liposomal side, but it lacked effect when added to the Na^+/transmitter-containing extracellular solution in cells (Fig. EV5A,B). Lack of extracellular Ca^{2+} effect on steady-state transport is likely due to competition to much stronger Na^+/H^+/transmitter coupled binding, while intra-liposomal Ca^{2+} inhibition could be due to facilitation of transmitter re-binding inside the liposome, as Ca^{2+} and transmitter binding are thermodynamically coupled.

From a physiological perspective, Ca^{2+}/transmitter coupling could play a regulatory role of Ca^{2+} in glutamate transport at tripartite synapses. Fine astrocytic processes at the synapse undergo transient increases in intracellular [Ca^{2+}] ($[Ca^{2+}]_i$), and modulate neuronal activity by increasing the amount of extracellular neurotransmitter available (Bazargani & Attwell, 2016). One potential mechanism linking these two phenomena is that at physiological glutamate intracellular-concentrations in astrocytes (mM), $[Ca^{2+}]_i$ transients could promote re-binding of the transmitter to EAATs, slowing down glutamate transport and increasing the amount of transmitter available at the synapse. Testing that and other hypotheses regarding the effect of extra- and/or intracellular Ca^{2+} on transmitter transport will require further experimentation, including time-resolved techniques.

Conformational changes associated to ion counter transport

284 Rb^+/Ba^{2+} bound $EAAT1_{CRYST}$ structure shows extensive and concerted conformational
285 changes on the extracellular half of the tranD compared to the Na^+/transmitter bound
286 state (Fig. 4B). The helical arms of HP2 and TM8a, and to a lesser extent the
287 extracellular part of TM3, TM6, and TM7 move outward and towards the scaD, while
288 the tip of HP2 is in an open position stabilized by a ~90-degree rotation of $M399_{379}$
289 sidechain towards the extracellular side, and separated from the tip of HP1 by as much
290 as ~11 Å. These movements expose the tranD core to the bulk, and enable hydration of
291 transmitter, Na^+, and H^+ binding sites, as well as distort sodium and transmitter
292 coordination (Fig. EV3): backbone and sidechain movements of $N398_{378}$ and $M399_{379}$,
293 at the conserved ^{398}NMDG motif, break Na^+ coordination at Na1-3, while those of HP2,
294 $T402_{382}$, and $R479_{459}$ disrupt transmitter's binding site.
295 The outward-facing open states seen in the structures of apo transporters (Rb^+/Ba^{2+} and
296 Ba^{2+} bound, respectively) are nearly identical (Fig. 5A), suggesting that the presence of
297 divalent cations in the crystallization buffer and/or crystal contacts might restrict
298 conformational changes of the tranD. Moreover, the open position of HP2 should
299 preclude transmembrane movements of the tranD and therefore, these structures likely
300 represent intermediates of the transport cycle that do not correspond to the K^+
301 translocation complex. To overcome these limitations, we determined the cryo-EM
302 structure of $EAAT1_{WT}$ purified in a K^+-based buffer (in the absence of other
303 monovalent and divalent coupled cations, as well as transmitter and $UCPH_{101}$) at an
304 overall ~ 4.0 Å resolution (Fig. 6A and Appendix Figure S3). The quality of the cryo-
305 EM map was better in the scaD than in tranD, likely reflecting the dynamic nature of
306 the latter (Appendix Figure S4), and we observed non-protein density for lipid or
307 detergent molecules at the scaD-tranD, as well as at inter-subunit interfaces suggesting
308 a regulatory role of lipids in tranD dynamics and trimer stability, respectively.

309 The cryo-EM structure shows a symmetric $EAAT1_{WT}$ trimer in an inward-facing state
310 with TM1a and TM1a' laying nearly parallel to the membrane, as well as two long beta-
311 strands between TM4b-c in the scaD protruding outside the membrane plane,
312 resembling the ones observed in human ASCT2 (Garaeva *et al.*, 2018). Consistent with
313 an elevator-like mechanism, the entire tranD undergoes a large movement that
314 translocates ligand binding-sites across the membrane, moving them by as much as 18
315 Å into the cytoplasmic side (Fig. 6B). Notably, tranD backbone adopts a different
316 conformation compared to that in Na^+/transmitter and Rb^+/Ba^{2+} crystal structures,
317 respectively (Fig. 6C). The extracellular half of the tranD, including HP2 and TM8a,
318 moves outward and towards the scaD expanding the tranD core compared to the
319 Na^+/transmitter bound state, but to a lesser extent than in the Rb^+/Ba^{2+} bound state. In
320 the cytoplasmic part of the tranD, TM7a moves away from HP1b at the level of Na1.
321 Yet, the tip of HP2 remains in contact with that of HP1 in a close position. The
322 concerted backbone movements of the tranD have several important mechanistic
323 implications: separation of HP2a, HP1b, and TM7a away from each other disrupts
324 backbone-atom coordination at Na1, Na2, and transmitter binding sites; concomitantly,
325 close proximity of HP1 and HP2 tips suggests that backbone carbonyl oxygen atoms of
326 $I423_{403}$ and/or $P424_{404}$ (HP2 tip) could contribute to counter-transported ion
327 coordination and occlusion at K_{CT} and therefore, that the tranD adopts an occluded state
328 competent for K^+ translocation.
329 To gain further insight into K^+-induced conformational changes outside the context of
330 the crystal lattice, we compared hydrogen-deuterium exchange linked to mass
331 spectrometry (HDX-MS) profiles of transporters at 25°C in Na^+/transmitter, and K^+
332 buffers, respectively (Fig. 6D and Appendix Figure S5, S6). $EAAT1_{WT}$ was not
333 amenable to HDX-MS analysis due rapid and irreversible unfolding at 25°C (Cirri *et*

al., 2018). Hence, we probed thermostabilized $EAAT1_{CRYST}$ using short deuterium-labeling time (1 min) to avoid unfolding events, and in the presence of $UCPH_{101}$ to restrict the conformational sampling to outward-facing states. Indeed, transporters in K^+ compared to Na^+/transmitter buffers showed a significant increase in HDX that localizes to the tip of HP1 and HP2, as well as the NMDG motif. These regions lack secondary structure, in both transmitter and counter-transported ion bound states, and contain key residues for Na^+ and transmitter coordination. Therefore, the observed changes in HDX imply that K^+ induces a significant increase in backbone hydration around the ligand binding sites, which is in excellent agreement with the conformational expansion of the tranD core observed in both crystal and cryoEM structures of apo transporters. Importantly, K^+-induced HDX changes reverted fully upon adding back Na^+/transmitter (Appendix Figure S6, control condition), demonstrating that transporters remain folded and respond to addition of ligands, and that observed HDX changes were not due to unfolding events of purified protein assayed at 25°C.

Discussion

Based on our structural and thermodynamic analyses, we propose a complete Na^+, H^+, K^+ coupled neurotransmitter transport mechanism that unifies a wealth of structural and biophysical data on SLC1 proteins (Fig. 7). In this mechanism, Na^+ binding to Na1-Na3 and protonation of $E406_{386}$ are thermodynamically coupled to transmitter binding and occlusion, and lead to the formation of the transmitter translocation complex, represented by $EAAT1_{CRYST}$ Na^+/transmitter bound crystal structure (Fig. 2A-D). In turn, K^+ binding to K_{CT} promotes self-occlusion, and formation of a K^+ translocation complex that excludes the transmitter, and it is represented by $EAAT1_{WT}$ cryo-EM structure (Fig. 6A,B).

Cooperative Na^+ binding to Na1 and Na3 in apo $EAAT1_{CRYST}$ enables substrate binding through re-arrangements of the NMDG signature motif that resemble those observed in SLC1 archaeal homologs (Guskov *et al.*, 2016; Verdon *et al.*, 2014), and this process is independent of both H^+ and K^+. Sodium-saturated apo-transporters undergo three key thermodynamically-coupled events that lead to substrate occlusion under HP2, and the formation of transmitter translocation complex: Na^+ binding to Na2 stabilizes HP2a against TM7a; protonation of $E406_{386}$ in TM7b enables hydrogen-bonding with HP2b; and transmitter binding secures closure of HP2 tip through direct coordination.

What are then the events that lead to formation of the K^+ translocation complex? Our results demonstrate counter-transported ion binding to K_{CT}, as well as hydration of the tranD core associated to K^+, strongly suggesting that these are key events to form the translocation complex. Importantly, K_{CT} fulfills two essential requirements as counter-transported ion binding site, first it precludes transmitter binding preventing futile transport cycles and potentially-cytotoxic release of glutamate and second, it promotes formation of a competent occluded state that enables elevator-like movements of the tranD, as suggested by the closed position of HP2 in $EAAT1_{WT}$ cryo-EM structure. Early reports predicted counter-transported ion binding sites similar to K_{CT} and mutually-exclusive transmitter and K^+ binding mechanisms (Holley & Kavanaugh, 2009; Verdon *et al.*, 2014; Wang *et al.*, 2013), in excellent agreement with our results. However, this view has been challenged by computational and functional studies that highlighted the role of Na1, as a likely counter-transported ion binding site (Kortzak *et al*, 2019; Wang *et al*, 2020). Several lines of experimental evidence presented here argue against that proposal: first, crystals grown in ~100 mM counter-transported ion (Rb^+) do not show anomalous-scattering peaks at Na1, revealing lack of ion occupancy at this site (Fig. 4B and Fig. EV2); second, K^+ concentrations up to 1.5 M have no

significant effect on cooperative Na^+ binding to apo transporters, arguably at Na1 and Na3, consistent with lack of K^+ affinity for these sites. Moreover, Ca^{2+} binds to Na3 with a K_D value in the low mM range, and induces a large increase in Na^+ apparent K_D (Fig. EV4). This supports the intuitive idea that significant occupancy of sodium sites by other cations impacts the apparent Na^+-binding parameter. Finally, in $EAAT1_{WT}$ cryo-EM structure, solved in the presence of 100 mM K^+ and absence of divalent cations, backbone movements of TM7a away from HP1 distort Na1 geometry, and it is not consistent with ion coordination at this site (Fig. 6C).

The close proximity of conserved $R479_{459}$ to K_{CT} argues that electrostatic shielding of its sidechain is required for K^+ occlusion and translocation, as suggested by reported apo EAAT3 structure (Qiu *et al.*, 2021) and MD simulations (Kortzak *et al.*, 2019), and hydration of the tranD core is likely key to this process. Both our crystal and cryo-EM structures of apo transporters show expansions of the tranD core around the ligand binding sites, and HDX-MS experiments confirmed increased hydration in this region. Water penetration in the tranD core should directly contribute to shield $R479_{459}$ charge, and more importantly induce deprotonation of $E406_{386}$, enabling ionic interactions between the two residues. Hydrogen-bonding between $R479_{459}$ and $T402_{382}$ could also contribute to electrostatic shielding (Fig. 4B). Consistently, $E406_{386}$ and $T402_{382}$ are highly conserved in EAAT orthologs, but are glutamine and alanine, respectively, in ASCT ones. Therefore, we propose a dual role of $E406_{386}$ and $R479_{459}$ in transport: in the transmitter translocation complex protonated $E406_{386}$ contributes to transmitter occlusion through hydrogen bonding with HP2, while $R479_{459}$ coordinates the gamma carboxylate group of the substrate. In the K^+ translocation complex, deprotonated $E406_{386}$ engages in ionic interactions with $R479_{459}$, enabling K^+ occlusion at K_{CT}. Equivalent mutations to E406Q in mammalian orthologs impair both H^+ and K^+

409 coupled transmitter transport (Grewer *et al.*, 2003; Kavanaugh *et al*, 1997), further
410 supporting the dual role of E406 in H^+ and K^+ coupling. Moreover, the cryo-EM
411 structure of inwardly-open EAAT3 in apo conditions shows equivalent residues to
412 E406 and R479 forming a salt bridge, although their roles in substrate occlusion seem
413 different (Qiu *et al.*, 2021), likely reflecting evolutionary differences among EAAT
414 isoforms.
415 Our findings shed light on controversial and important aspects of EAATs transport
416 cycle, and suggest novel mechanisms to regulate glutamate levels at tripartite synapses.

Methods

Protein expression and purification

Genes encoding EAAT1 and thermostabilized $EAAT1_{CRYST}$ constructs were cloned into the pcDNA3.1(+) plasmid (Invitrogen) as previously described with N-terminal Strep-tag II affinity tag, eGFP and PreScission site(Canul-Tec *et al.*, 2017). Protein was expressed in HEK293F cells (Thermo Fisher Scientific) grown in Freestyle293 medium (Invitrogen) at 37 °C to densities of 2.5 x 10^6 cells ml^{-1}. Cells were transiently transfected using 7.5 mg ml^{-1} polyethylenimine (PEI) (Polysciences) and 2.5 mg ml^{-1} of DNA. Transfected cells were diluted with an equivalent volume of Freestyle293 medium 8 h post-transfection and treated with 10 mM of sodium butyrate (Sigma) 12 h after dilution. Cells were harvested by centrifugation 48 h after transfection, resuspended at 1:4 (w/v) ratio in cold buffer containing 50 mM HEPES/Tris-base, pH 7.4, 50 mM NaCl, 1 mM L-asp, 1 mM EDTA, 1 mM Tris(2-carboxyethyl) phosphine (TCEP), 1 mM Phenylmethylsulfonyl fluoride (PMSF) and 1:200 (v/v) dilution of mammalian protease inhibitor cocktail (Sigma), and flash-frozen in liquid nitrogen for storage at -80 °C.

Cell suspension was thawed and diluted 1:2 volumes in buffer complemented with 350 mM NaCl, 10% glycerol, 1% dodecanoyl sucrose (DDS, Anatrace) and 0.2% Cholesteryl Hemisuccinate Tris Salt (CHS, Anatrace). After 1 h detergent extraction, cell debris was removed (4,500 *g*, 0.5 h), and the supernatant cleared (186,000 g for 1 h). Clear lysate was incubated with Strep-Tactin Sepharose High Performance resin (GE Healthcare) previously equilibrated with buffer containing 50 mM HEPES/Tris-base, pH 7.4, 200 mM NaCl, 1 mM L-asp, 1 mM TCEP, 5% glycerol, 0.05% DDS and 0.01% CHS, for 2 h. In crystallization experiments of apo transporters in Rb^+ or choline buffers (see below) resin incubation was preceded by an ultracentrifugation membrane-

wash step, as described before (Canul-Tec *et al.*, 2017). Resin was washed with 20 column volumes (CV) of equilibration buffer supplemented with 1:1:1 lipid mixture of 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphoethanolamine (POPE) and 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphoglycerol (POPG) (Avanti Polar Lipids) at total concentration of 25 μM. Protein was eluted with buffer supplemented with 2.5 mM D-desthiobiotin (Sigma), and subjected to N-term PreScission cleavage during 2 h. The sample was concentrated with 100-kDa cutoff Amicon centrifugal filter unit (Millipore) and injected into a size-exclusion chromatography (SEC) column Superose 6 10/300 (GE Healthcare), equilibrated in different buffers (see below). All purification steps were carried out at 4 °C.

Intrinsic-tryptophan fluorescence binding assay

PreScission-treated $EAAT1_{CRYST}$ and mutant transporters were further purified by SEC in buffer containing: HEPES/Tris-base, pH 7.4, 200 mM NaCl, 1 mM L-asp, 1 mM TCEP, 5% glycerol, 0.05% DDS, 0.01% CHS and 25 μM lipid mix. Peak fractions were concentrated using a 100-kDa cutoff Amicon centrifugal filter, and then diluted 10-fold in buffer: 50 mM HEPES/Tris-base, pH 7.4, 200 mM ChCl, 1 mM TCEP, 0.05% DDS and 0.01% CHS. This procedure was repeated three times to ensure buffer exchange. Binding experiments started by further diluting transporters ~ 100-fold in a 1-ml quartz cuvette filled with the above-mentioned Ch^+-based buffer to reach 2-4 μM final protomer concentration. In L-asp titrations, final NaCl or $CaCl_2$ concentrations were added to the cuvette as indicated in the Figures. To assay binding of ligands in the presence of $UCPH_{101}$, 20 μM final concentration was added to both protein sample and cuvette, and allowed for ~30 min equilibration time. Binding experiments at different

pH values were done by substituting HEPES/tris-base with MES/tris-base (pH 5 and 6), or Tris/HCl (pH 9 and 10) in the cuvette buffer.

Experiments were done at 25 °C under stirring. Intrinsic tryptophan fluorescence was excited at 280 nm, and emission recorded at 325 nm using a QuantaMaster 40 spectrofluorometer (Horiba). Protein samples were equilibrated for 2-min in the cuvette, before ligand addition at different concentrations, and fluorescence emission was averaged over the last 10s after equilibration. Fractional fluorescence changes were fitted to the Hill equation. Data analysis, fitting, and figures were done with SigmaPlot 12 (Systat Software, Inc).

Crystallization and structure determination

PreScission-treated transporters were supplemented with 100 µM $UCPH_{101}$ (Abcam) for 30 minutes at 4 °C, and further purified by SEC in buffers at pH 7.4 (HEPES/Tris-base), containing 1 mM TCEP, 5% glycerol, 100 µM $UCPH_{101}$, 0.25% decanoyl sucrose (DS, Merck Millipore), 0.05% CHS, 25 µM lipid mix, and one of the following: 200 mM Na and 1 mM L-asp (Na^+/asp-bound state); 200 mM RbCl (Rb^+/Ba^{2+}-bound state); or 200 mM ChCl (Ba^{2+}-bound state). Peak fractions were concentrated to 4 mg ml^{-1}, supplemented with 0.2% n-Octyl-b-D-glucopyranoside (BOG, Anatrace) and 0.04% CHS, and used immediately for crystallization. Vapor-diffusion hanging-drop crystallization and cryogenic conditions were as previously described (Canul-Tec *et al.*, 2017), using equal volumes of sample and a reservoir solution containing 100 mM Tris, pH 8.2, 28-32% (v/v) PEG 400, 50 mM $CaCl_2$ and 50 mM $BaCl_2$.

Complete and highly-redundant X-ray diffraction datasets were collected at tunable beamlines PROXIMA-1 (SOLEIL synchrotron, St. Aubin, France), as well as ID29 and ID30B (European Synchrotron Radiation Facility, Grenoble, France). $EAAT1_{CRSYT}$ and $EAAT1_{CRYST\text{-}II}$ crystals purified in Rb^+- or Ch^+-based buffers were smaller and typically

658 diffracted at significant lower resolutions (> 6Å) than those purified in Na^+/asp-based
659 buffers (< 4 Å), and they required larger crystal-screening efforts to collect datasets at
660 the reported resolutions.
661 Diffraction datasets were processed as described before (Canul-Tec *et al.*, 2017) using
662 XDS package (Kabsch, 2010) and AIMLESS (Evans & Murshudov, 2013). All crystals
663 belonged to the same space group ($P6_3$), and diffracted anisotropically. Anisotropy
664 correction was made with STARANISO (Global Phasing Lim.). Appendix Table S1
665 and S2 include comparison of reflection statistics before and after anisotropic
666 correction reflecting complete sampling of reciprocal space, as well as refinement
667 statistics of reflections along crystallographic axes. Corrected anisotropic amplitudes
668 were used for molecular replacement in PHASER (McCoy *et al*, 2007), using TranD
669 and ScaD of $EAAT1_{CRYST}$ or $EAAT1_{CRYST\text{-}II}$ (PDB codes 5LLM and 5LM4,
670 respectively) as independent search models. Final electron density maps were obtained
671 through rounds of manual building in COOT (Emsley *et al*, 2010) and refinement in
672 Buster (Blanc *et al*, 2004), until reaching good crystallographic statistics and
673 stereochemistry (Appendix Table S1 and S2). Anomalous difference maps were
674 calculated with SHELX and ANODE (Thorn & Sheldrick, 2011) using diffraction data
675 with high-resolution cutoff of 6Å, and without anisotropic correction.
676 In the Na^+/asp-bound $EAAT1_{CRYST}$ structure, we modelled extra electron density in the
677 tranD (TM7-HP2 loop, residues 397-403), and in the scaD N-terminus (TM1a' helix,
678 residues 26-36). Rounds of refinement with extended transporter models incrementally
679 improved the quality of 2Fo-Fc maps, and yielded three peaks in the Fo-Fc omit maps
680 that localize to conserved Na1-Na3. We modelled 3 Na^+ bound to the transporter at
681 these peaks. We also calculated anomalous differences maps, and observed a single
682 anomalous peak on the surface of the ScaD, nearby residue Q245 (TM5), that we

683 modeled as a bound barium ion with low occupancy (0.35). Our functional and
684 structural data do not support functional roles of this ion on the transport mechanism.
685 Rb^+/Ba^{2+} and Ba^{2+} bound electron density maps of apo transporters, respectively, were
686 lower resolution compared to Na^+/asp-bound. This is likely due to the observed
687 conformational re-arrangements of the tranD that break or weaken crystal-lattice
688 contacts between TM1a' and extracellular tranD surface of a crystallographic-
689 symmetry mate. Consistently, in Rb^+/Ba^{2+} and Ba^{2+} bound structures, respectively,
690 TM7-HP2 loop and TM1a' were not modeled due to lack of density in these regions.
691 Rb^+ at K_{CT}, as well as Ba^{2+} at Na3 were modeled based on anomalous difference maps
692 from datasets at maximum and off-maximum Rb^+ absorption wavelengths,
693 respectively.
694 Atomic model validation was performed with Molprobity (Chen *et al*, 2010). Structural
695 figures were prepared with PyMOL Molecular Graphics System (Schrodinger, LLC).
696 **Cryo-EM sample preparation, data collection and processing**
697 $EAAT1_{WT}$ (Uniprot P43003) sequence was mutated at predicted N-glycosylation sites
698 (N206T, and N216T), and expressed and purified as mentioned above, with SEC buffer
699 containing: 50 mM HEPES/Tris-base, pH 7.4, 100 mM KCl, 1 mM TCEP, 0.0084%
700 glycol-diosgenin (GDN), and 0.0017% CHS. Peak fractions were concentrated at 4-5
701 mg ml^{-1} and spotted immediately on glow-discharged Quantifoil R1.2/1.3 Au grids
702 (Quantifoil Micro Tools GmbH), and plunge frozen using a Vitrobot Mark IV (FEI) at
703 4°C under 100% humidity. Grids were stored in liquid nitrogen.
704 Cryo-EM micrographs were recorded on a Titan Krios electron microscope (Thermo
705 Fisher Scientific) operated at 300 kV, equipped with GatanK2 direct electron detector
706 (Appendix Table S3). Movies were collected on counting mode automatically using
707 SerialEM (Mastronarde, 2005) with a pixel size of 0.814 Å. The defocus range was -

0.8 to -2.0 μm and each movie contained 40 frames with a dose per frame of 1.03 electrons/Å^2, and total exposure time 8 s.

Single-particle data processing was done in cryoSPARCv3.1.0 (Punjani *et al*, 2017) (Appendix Figure S3). Beam-induced patch-motion correction, and patch contrast transfer function estimation were done with in-built cryoSPARC routines, respectively. 2,298,481 auto-picked particles were 2x binned and extracted from 13,607 manually-selected movies. Initially, 517,319 selected from 2D-classification were subjected to several rounds of *ab initio* classification. This yielded a 3D reconstruction from 71,296 particles in which the transmembrane helices of the transporter were evident, but refined at > 6 Å using unbinned particles for non-uniform refinement (Punjani *et al*, 2020). We then input those *ab initio* volumes to re-classify the original set of 2,298,481 2x-binned particles using several rounds of heterogenous refinement. In the first round of heterogenous refinement, two unrelated cryo-EM maps were included as templates to aid discarding bad particles. From this, 433,972 particles were selected and unbinned for further rounds of heterogenous refinement and *ab initio* classification. An *ab initio* 3D reconstruction from a final set of 34,433 particles yielded a map at an overall ~4.0 Å, after non-uniform refinement with C3 symmetry imposed. The map quality was significantly better in the region corresponding to the scaD than that of the tranD. This is somehow expected, since the three tranDs undergo independent conformational changes both relative to the three scaDs, as well as locally.

For model building, the scaD and tranD of Rb^+/Ba^{2+} bound X-ray structure were fitted into the EM map as separate rigid-bodies using Chimera. This initial model was then adjusted manually in COOT preserving the secondary structure observed in the crystal. We also used the cryoEM structure of ASCT2 (PDB 6GCT) (Garaeva *et al.*, 2018) as a reference for regions of the tranD that were not modeled in the crystal structure and

for which we had density in the cryo-EM map. We omitted conserved residues ^{398}NMD^{400} in the final cryo-EM model due to lack of density in this region. The final model was refined in PHENIX (Adams *et al*, 2010), and figures made with UCSF Chimera (Pettersen *et al*, 2004), UCSF ChimeraX (Goddard *et al*, 2018), and PYMOL.

Radioactive substrate transport assays

Liposomes were formed at 5:1 molar ratio of POPC and Cholesteryl Hemisuccinate (Avanti Polar Lipids) and resuspended at 8 mg ml^{-1} in buffer containing 50 mM HEPES/Tris, pH 7.4 and 200 mM NaCl, and pre-treated with 1.3% DDS and 0.26% CHS for 1 h. eGFP-EAAT1$_{CRYST}$ fusion construct was purified by SEC in buffer containing: HEPES/Tris-base, pH 7.4, 200 mM NaCl, 1 mM L-asp, 1 mM TCEP, 5% glycerol, 0.05% DDS, 0.01% CHS and 25 μM lipid mix. Purified eGFP-EAAT1$_{Cryst}$ was mixed with destabilized liposomes at a 1:40 (w/w, protein/lipid ratio) for 1 h. Detergent removal was repeated three times with Biobeads SM-2 (BioRad) at 100 mg ml^{-1} and at 4 °C. Proteoliposomes were loaded with internal buffer (50 mM HEPES/Tris-base, pH 7.4 buffer, 200 mM KCl and 1.25% glycerol) through 10 freeze-thaw cycles followed by 10 extrusion cycles through 400-nm polycarbonate membranes (Avanti Polar Lipids). Proteoliposomes were centrifuged (164,300 *g*, 30 min at 4 °C) and resuspended at 100 mg of lipids ml^{-1} in buffer containing 50 mM HEPES/Tris-base, pH 7.4, 200 mM choline chloride (ChCl) and 1.25% glycerol for immediate use.

Substrate uptake was performed at 37°C for 30 min, and initiated by diluting proteoliposomes 10-fold into buffer containing 50 mM HEPES/Tris-base, pH 7.4, 200 mM NaCl, 1.25% glycerol, 50 μM L-glutamate and 10 μM L-[^{14}C(U)]-glutamate (PerkingElmer). Uptake was stopped with 5-fold dilution of proteo-liposome mix into ice-cold buffer (50 mM HEPES/Tris-base, pH 7.4, 200 mM ChCl and 1.25% glycerol)

followed by immediate filtration and wash on nitrocellulose 0.22-µm filters (Merck Millipore). Background radioactivity was estimated on each sample using proteoliposomes diluted in buffer containing 200 mM ChCl, instead of NaCl, and subtracted during analysis. Filter membranes were transferred to scintillation cocktail Ultima Gold (PerkinElmer), and radioactivity quantified using Tri-Carb 3110TR counter (PerkinElmer). This setup was used to calibrate different batches of radioactive L-glutamate source. Protein quantification was done in an Infinite M1000Pro microplate reader (Tecan) using calibrated eGFP fluorescence intensity.

Uptake experiments at different pH values were done with modified external buffers containing: 50 mM MES/Tris-base pH 6.0, HEPES/Tris-base pH 7.4, or 50 mM Tris/HCl pH 9.0 or 10.0. Counter-transported ions were probed by exchanging KCl in the intraliposomal buffer for equal concentrations of RbCl, or ChCl, or 125 mM ChCl and 50 mM $CaCl_2$ through freezing-thawing cycles. Reported values are means of at least three independent experiments, each one measured at least in triplicates.

In HEK293-cells uptake experiments, cells were collected 36-44 h after transfection, washed two times, and resuspended at a density of 50×10^6 cells ml^{-1} in buffer 11 mM HEPES/Tris-base, pH 7.4, 140 mM ChCl, 4.7 mM KCl, 2.5 mM $CaCl_2$, 1.2 mM $MgCl_2$, and 10 mM D-glucose, for immediate use. Substrate uptake was performed as described in liposomes with some variations. For experiments shown in Appendix Figure 1, reaction time was 1 min in buffer containing 11 mM HEPES/Tris-base, pH 7.4, 140 mM NaCl, 4.7 mM KCl, 2.5 mM $CaCl_2$, 1.2 mM $MgCl_2$, 10 mM D-glucose, 50 µM L-glutamate, and 5 µM [^{14}C] L-glutamate. For experiments shown in Fig. EV5, reaction time was 15 min in buffer containing 11 mM HEPES/Tris-base, pH 7.4, 140 mM NaCl, 4.7 mM KCl, 5 mM $CaCl_2$, 10 mM D-glucose, and either 50 µM L-glutamate/10 µM

782 [^{14}C] L-glutamate, or 15 μM L-glutamate/5 μM [^{14}C] L-glutamate. In Mg^{2+}-containing
783 conditions, all Ca^{2+} was substituted for Mg^{2+}.
784 Cells were filtered using 0.8-μm nitrocellulose filters, and background radioactivity
785 was estimated from cells transfected with empty vector in NaCl reaction buffer, and
786 subtracted from the uptake data. Reported values are means of three independent
787 experiments measured in duplicates.
788 **Hydrogen-deuterium exchange mass spectrometry (HDX-MS)**
789 PreScission-treated $EAAT1_{CRYST}$ was further purified by SEC in buffer containing:
790 HEPES/Tris-base, pH 7.4, 200 mM NaCl, 1 mM L-asp, 1 mM TCEP, 5% glycerol,
791 0.05% DDS, 0.01% CHS, 25 μM lipid mix, and 100 μM $UCPH_{101}$. This sample
792 constitutes reference Na^+/L-asp-bound state. K^+-bound state was obtained by two
793 cycles of 10-fold dilution-concentration of reference samples in buffer: 50 mM
794 HEPES/Tris-base, pH 7.4, 200 mM KCl, 1 mM TCEP, 100 μM $UCPH_{101}$, 0.05% DDS
795 and 0.01% CHS. To probe reversibility of K^+-induced HDX changes, a Na^+/L-asp-
796 bound control state was generated by addition of 200 mM NaCl and 1 mM L-asp to the
797 K^+-bound state. Final concentration of all samples for HDX-MS analysis was ~0.8 mg
798 ml^{-1}.
799 Peptide map was generated using nanoLC-MS/MS. 20 pmol of reference transporters
800 were digested for 2min in 0.75% formic acid using an immobilized pepsin column (2.1
801 x 20 mm, Affipro). Peptic peptides were collected and purified onto C18 Stage-Tips
802 before nanoLC-MS/MS analysis using an EASY-nLC^{TM} 1200 system (Thermo-
803 Scientific) coupled to the nanoelectrospray ion source of an Orbitrap Q-Exactive Plus
804 mass spectrometer (Thermo-Scientific). Peptides were loaded on an in-house packed
805 nano-HPLC column (75 μm x 25 cm) with C18 resin (Aeris PEPTIDE XB-C18, 1.7μm
806 particles, 100 Å pore size, Phenomenex) and separated by reverse-phase

chromatography at 250 nL/min using a gradient of acetonitrile with 0.1% formic acid. The Orbitrap mass spectrometer was set up in data-dependent acquisition mode. After a survey scan in the Orbitrap (resolution 60,000 at m/z 400), the 10 most intense precursor ions were selected for HCD fragmentation with a normalized collision energy set up to 28 (resolution 30,000). Only charge states between 1 and 10 were selected and a dynamic exclusion of 20 s was set. NanoLC-MS/MS data were processed automatically using Mass Spec Studio v1.3.2(Rey *et al*, 2014) to identify peptides with the following parameters: 4-40 amino acid length, charge states between 1 and 5, mass accuracy of 7 ppm for both MS and MS/MS, and a false discovery rate (FDR) of 5%.

Deuterium exchange was initiated by diluting 64 pmol of purified transporter with the appropriate labeling buffers at 25°C. These buffers reached final level of 80% D_2O and otherwise were as described above for reference, K^+-bound and control states, respectively. 30 pmol transporter aliquots were removed at 60s, and immediately quenched with a cold acidic solution (1.25% formic acid) to decrease the pH to 2.5. Samples were then snap-frozen in liquid nitrogen and stored at -80°C until LC-MS analysis.

Quenched samples were rapidly thawed and injected into a cooled ACQUITY UPLC M-Class HDX system (Waters) maintained at 4°C. 15 pmol of transporter were online digested for 3 min at 20°C and 80 µL/min of solvent A (0.15% formic acid (v/v) in water) using an immobilized pepsin column (2.1 x 20 mm, Affipro). Peptic peptides were desalted onto a C18 trap column (Kinetex® EVO C18, 2.6µm, 100Å, 2.1 x 20 mm, Phenomenex) at a flow rate of 80 µL/min of solvent A and then separated at 70 µL/min by a linear gradient from 10 to 60% of solvent B (0.15% formic acid (v/v) in acetonitrile) in 11 min using a C18 analytical column (Kinetex® EVO C18, 1.7µm, 100Å, 1 x 100 mm, Phenomenex). The pepsin column was washed with 1.5M

guanidinium chloride / 5% acetonitrile / 1% formic acid. Blank injections were performed between each run to ensure the absence of carry-over. The LC flow was directed to a Synapt^{TM} G2-Si HDMS^{TM} mass spectrometer (Waters) equipped with an electrospray ionization (ESI) source. Mass spectra were acquired in positive and resolution mode over the m/z range of 300-1500 with 0.5 s scan time.

Data analysis was performed on biological triplicates using at least five replicates per transporter state. Deuterium uptake values were calculated for each peptide using Mass Spec Studio v1.3.2 and no adjustment was made for back-exchange. Student t-tests and Woods plots were performed for each transporter state using the embedded statistical module in Mass Spec Studio v1.3.2 with the following parameters: standard deviation cutoff = 2 and 1-p cutoff = 0.99.

Data availability

Atomic coordinates of crystal structures were deposited in the RCSB Protein Data Bank (PDB) under the following accession numbers: Na^+/transmitter bound $EAAT1_{CRYST}$ (7AWM; https://doi.org/10.2210/pdb7AWM/pdb); Na^+/transmitter bound $EAAT1_{CRYST}$-E386Q (7AWQ; https://doi.org/10.2210/pdb7AWQ/pdb); Rb^+/Ba^{2+} bound $EAAT1_{CRYST}$ (7AWN; https://doi.org/10.2210/pdb7AWN/pdb); Rb^+/Ba^{2+} bound $EAAT1_{CRYST-II}$ (7AWP; https://doi.org/10.2210/pdb7AWP/pdb); and Ba^{2+} bound $EAAT1_{CRYST-II}$ (7AWL; https://doi.org/10.2210/pdb7AWL/pdb). Atomic coordinates and cryo-EM map of $EAAT1_{WT}$ structure were deposited in the PDB (7NPW; https://doi.org/10.2210/pdb7NPW/pdb), and Electron Microscopy Data Bank (EMD-12524; https://www.emdataresource.org/EMD-12524).

Code availability

In-house script to facilitate reflection processing with STARANISO (P.L.) is available at

886 **Figure 1 Na^+ and transmitter binding**
887 A. Tryptophan-fluorescence time course associated to Na^+ (blue) and K^+ (black)
888 binding, respectively, to detergent-purified apo $EAAT1_{CRYST}$ at pH 7.4. Horizontal and
889 vertical scale bars represent time and $\Delta F/F_0$, respectively.
890 B. Tryptophan-fluorescence time course associated to L-asp binding in presence of 1
891 mM (blue) and absence (black) of Na^+, respectively, at pH 9.
892 C. Na^+ binding isotherms of $EAAT1_{CRYST}$ at pH 7.4 in the presence (pink) and absence
893 (blue) of $UPCH_{101}$. Mutation $D400_{380}N$ at Na3 strongly impairs Na^+ binding (green).
894 Solid lines represent fits of Hill equation.
895 D. Log-log plot of L-asp K_D as a function of Na^+ concentration. Empty circles are K_D
896 values (n=20) at pH=9.0 in the absence of $UCPH_{101}$ (blue), and solid line is the fit of a
897 straight line. For comparison, average L-asp K_D at 1 mM Na^+ in the presence pf of
898 $UPCH_{101}$ is also shown (n=3; red).
899 Data information: in (C) symbols represent average and s.e.m. values of at least three
900 independent titrations. In (D), blue symbols represent individual K_D values from *n*
901 number of independent titrations, and red symbol represents average and s.e.m values
902 from three experiments.

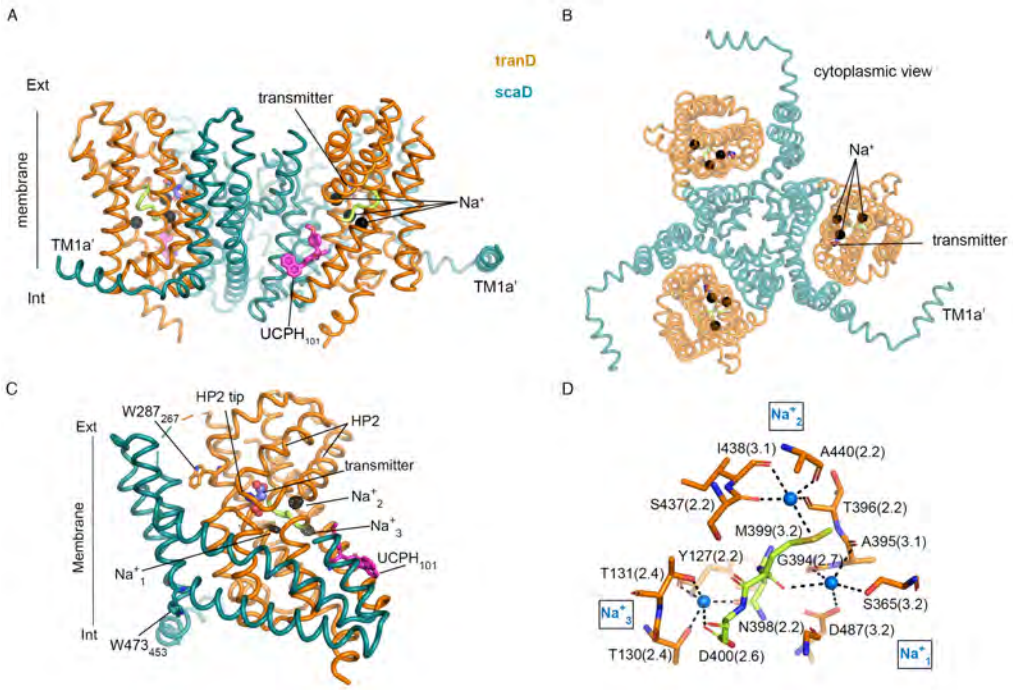

Figure 2 EAAT1$_{CRYST}$ Na^+/transmitter bound structure

A, B. Views of EAAT1$_{CRYST}$ trimer in outward-facing Na^+/transmitter-bound state, including N-term helix TM1a'.

C. EAAT1$_{CRYST}$ protomer viewed from the membrane with tranD orange, scaD teel (TM4a,b omitted), and ^{398}NMDG motif green. Fo-Fc Na^+-omit map contoured at 3.5σ (black mesh) around the tranD core.

D. Coordination details of three Na^+-bound (blue sphere) to EAAT1$_{CRYST}$. Residue numbering corresponds to EAAT1$_{WT}$, and the coordination distance (angstrom) is in parenthesis.

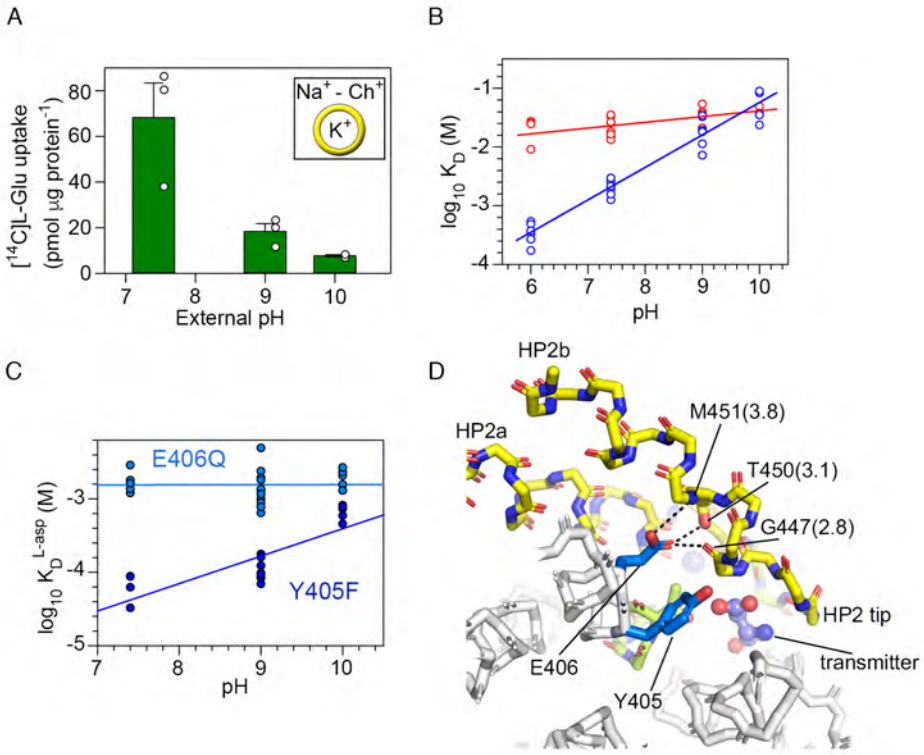

Figure 3 H^+ and transmitter binding

A. Na^+-induced L-glutamate uptake by purified $EAAT1_{CRYST}$ reconstituted in liposomes loaded with K^+. Choline (Ch^+) condition was subtracted to the Na^+ condition.
B. Log-log plots of Na^+ (red, n=19) and L-asp (blue, n=27) K_D, as a function of pH at $[Na^+]$=0.5 mM. Na^+ (n=10) and L-asp (n=7) titration data at pH 7.4 and 9.0, respectively, are also reported in Fig. 1. Solid lines are fits of straight lines.
C. Log-log plots of L-asp K_D for $EAAT1_{CRYST}$-$E406_{386}Q$ (light blue, n=24) and $EAAT1_{CRYST}$-$Y405_{385}F$ (dark blue, n=18), as a function of pH at $[Na^+]$=0.5 mM..
D. Potential H^+-bond network between protonated $E406_{386}$ (TM7b) and residues in HP2b in $EAAT1_{CRYST}$ transmitter-bound structure. HP2 is depicted in yellow and the ^{398}NMDG motif in green. Residue numbering corresponds to $EAAT1_{WT}$, and the interatomic distance (angstrom) is parenthesis.
Data information: in (A) bar plots depict averages and s.e.m. values of three independent experiments (empty circles) performed in triplicate. In (B,C) symbols represent individual K_D values from *n* number of independent titrations.

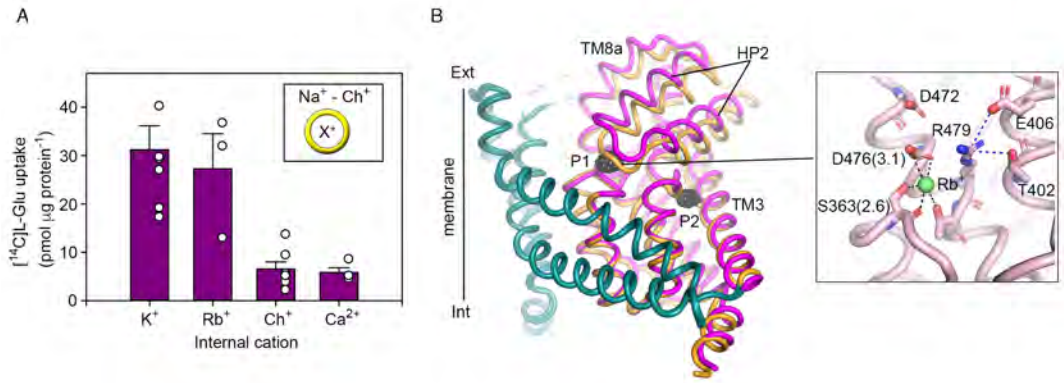

Figure 4 Counter-transported ion binding site

A. Purified $EAAT1_{CRYST}$ takes up L-glutamate in liposomes loaded with K^+ or Rb^+, but not with choline (Ch^+), or with Ch^+ and Ca^{2+}. Plots depict data as in Fig. 3A.

B. Superimposition of Na^+/transmitter and Rb^+ bound $EAAT1_{CRYST}$ structures, respectively, with tranD depicted in orange (Na^+/transmitter) and pink (Rb^+). TM4 and $UCPH_{101}$ are omitted for clarity. Black mesh depicts anomalous-difference map contoured at 3.5σ around the tranD. Rb^+ coordination is shown in the inset. Residue numbering corresponds to $EAAT1_{WT}$, and the coordination distance (angstrom) is parenthesis.

Data information: in (A) bar plots depict averages and s.e.m. values of three independent experiments (empty circles) performed in triplicate.

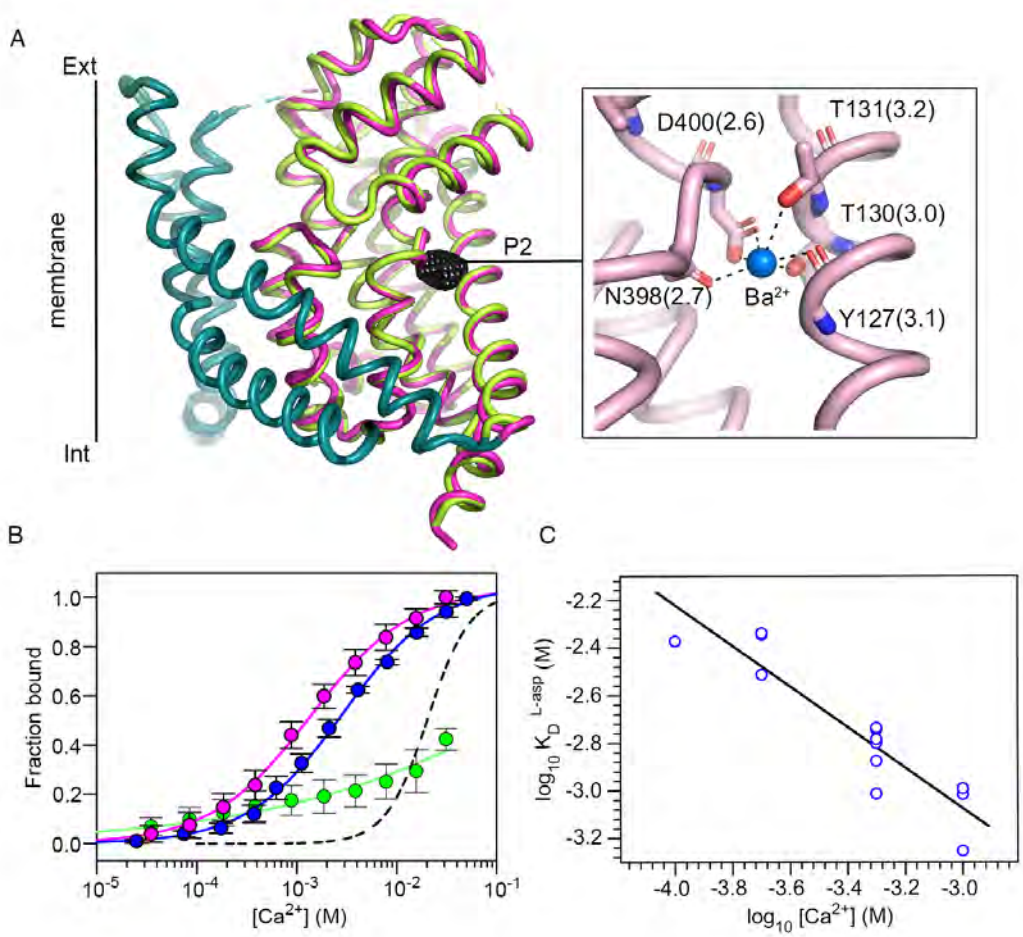

Figure 5 Divalent cation binding

A. Superimposition of Rb^+/Ba^{2+} and Ba^{2+} bound $EAAT1_{CRYST}$ structures with tranD depicted in pink and green, respectively, and TM4 removed for clarity. Black mesh depicts anomalous-difference map in the absence of Rb^+ contoured at 4σ around the tranD, and inset shows details of Ba^{2+} coordination at Na3. Residue numbering corresponds to $EAAT1_{WT}$, and the coordination distance (angstrom) is parenthesis.

B. Ca^{2+} binding isotherms of $EAAT1_{CRYST}$ at pH=7.4 in the presence (pink) and absence (blue) of $UPCH_{101}$. Mutation $D400_{380}N$ at Na3 strongly impairs Ca^{2+} binding (green). Symbols represent average and s.e.m. values of at least three independent experiments. Solid lines represent fits of Hill equation and dashed line is the fit in Fig. 1C (blue line) corresponding to Na^+ binding.

C. Log-log plot of L-asp K_D as a function of Ca^{2+} (n=13).

Data information: in (B) symbols represent average and s.e.m. values of at least three independent titrations. In (C), blue symbols represent individual K_D values from *n* number of independent titrations.

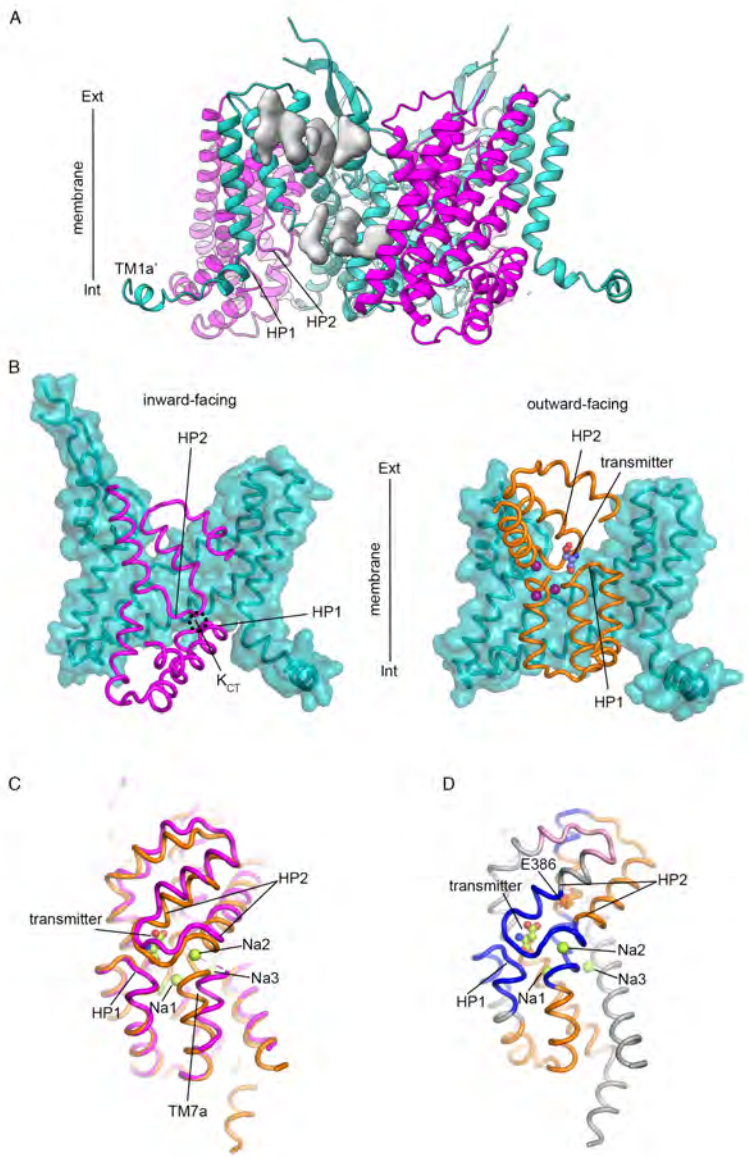

Figure 6 CryoEM structure and HDX-MS changes in K^+ buffer

A. CryoEM structure of $EAAT1_{WT}$ trimer with tranDs and scaDs depicted in magenta and teal, respectively. Non-protein extra density corresponding to lipid/detergent molecules is depicted in grey.

B. Comparison of $EAAT1_{WT}$ (left) and $EAAT1_{CRYST}$ (right) structures in inward- and outward-facing states, respectively. Several TMs were removed for clarity.

C. TranDs from $EAAT1_{WT}$ (magenta) and $EAAT1_{CRYST}$ (orange) structures are overlapped using HP1 as reference.

D. K^+-induced HDX increase (blue) and decrease (pink) in $EAAT1_{CRYST}$ is mapped on Na^+/transmitter-bound tranD structure. Unchanged regions (orange) and those outside HDX-MS sequence coverage (grey) are also shown.

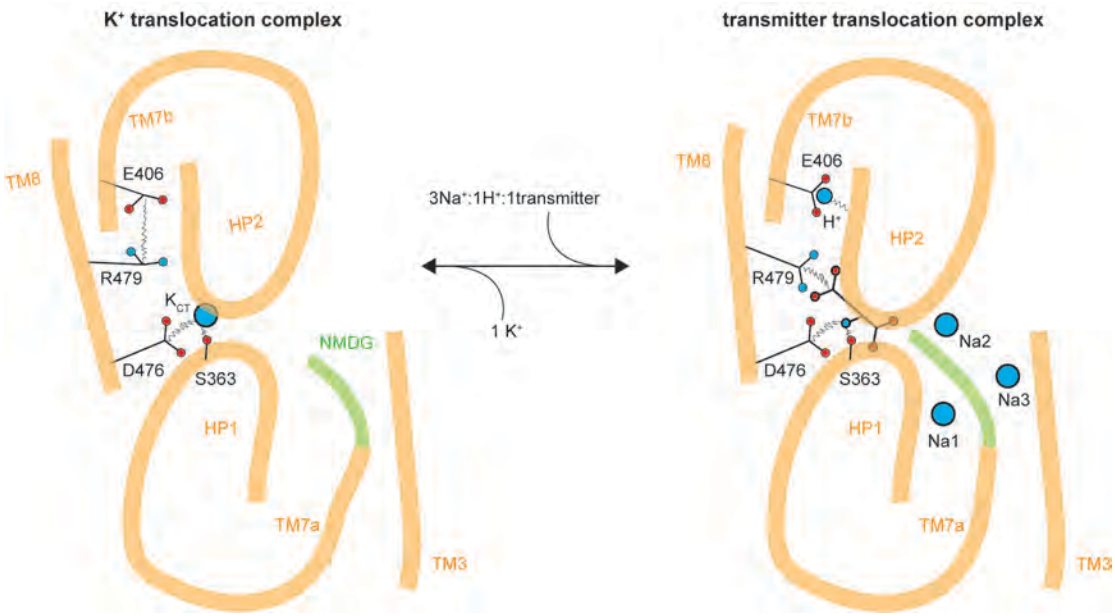

Figure 7 EAAT1 $3Na^+/1H^+/1K^+$ coupled transport mechanism

Cartoon representation of Na^+/H^+/transmitter, and K^+ translocation complexes, respectively.

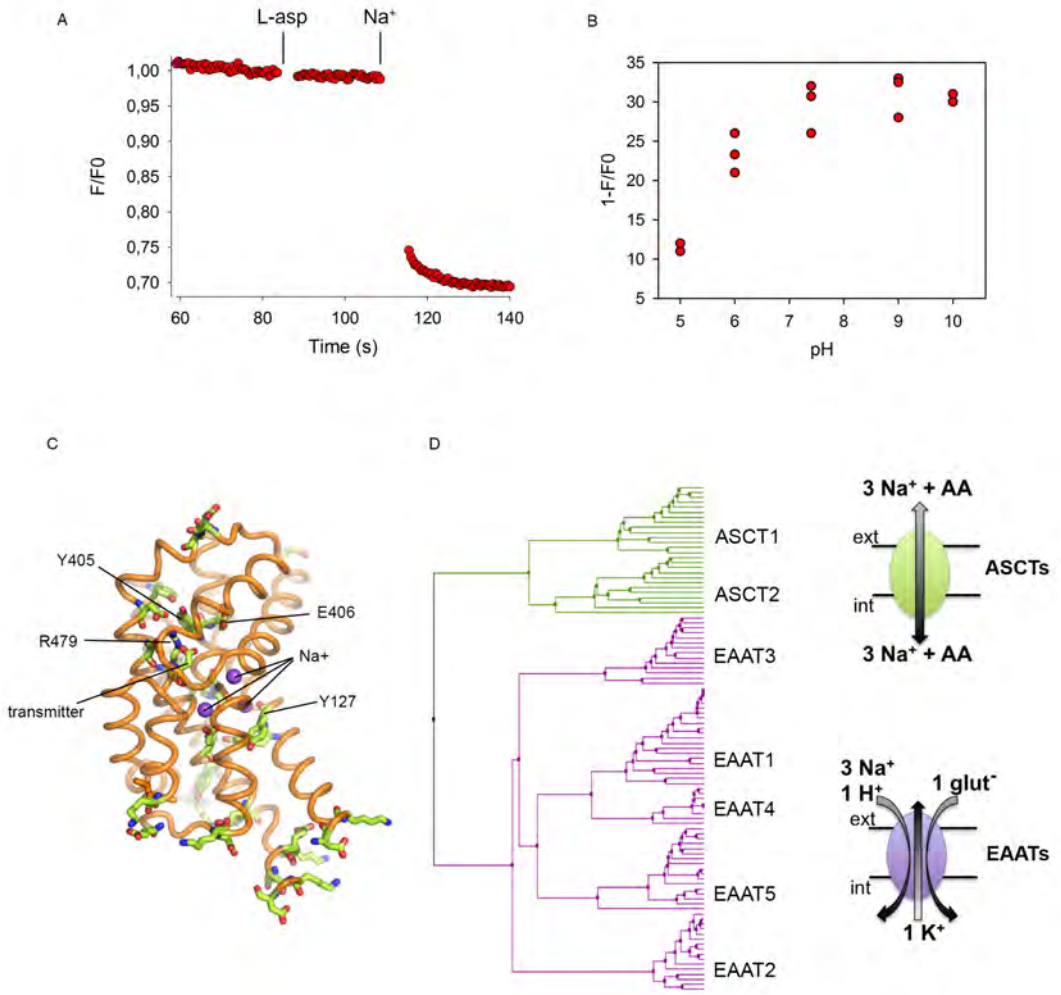

Figure EV1 Proton binding to conserved ionizable sidechain in EAAT$_{CRYST}$

A. EAAT1$_{CRYST}$ tryptophan-fluorescence time-course at pH 10 upon addition of saturating concentrations of L-asp, and Na^+.

B. Percentage of L-asp/Na^+ induced total fluorescence change ($1-F/F_0$) decreases at pH values below neutral.

C. Out of >30 ionizable sidechains (green sticks) in the tranD of EAAT1$_{CRYST}$ only four (labelled with residue number) are strictly conserved in EAATs, and not in ASCTs.

D. Phylogenetic tree from 101 tranD sequences of representative vertebrate species (Gesemann *et al.*, 2010) calculated with Jalview (BLOSUM62 average distance). Transport stoichiometry of EAATs and ASCTs vertebrate proteins is depicted in cartoon representation.

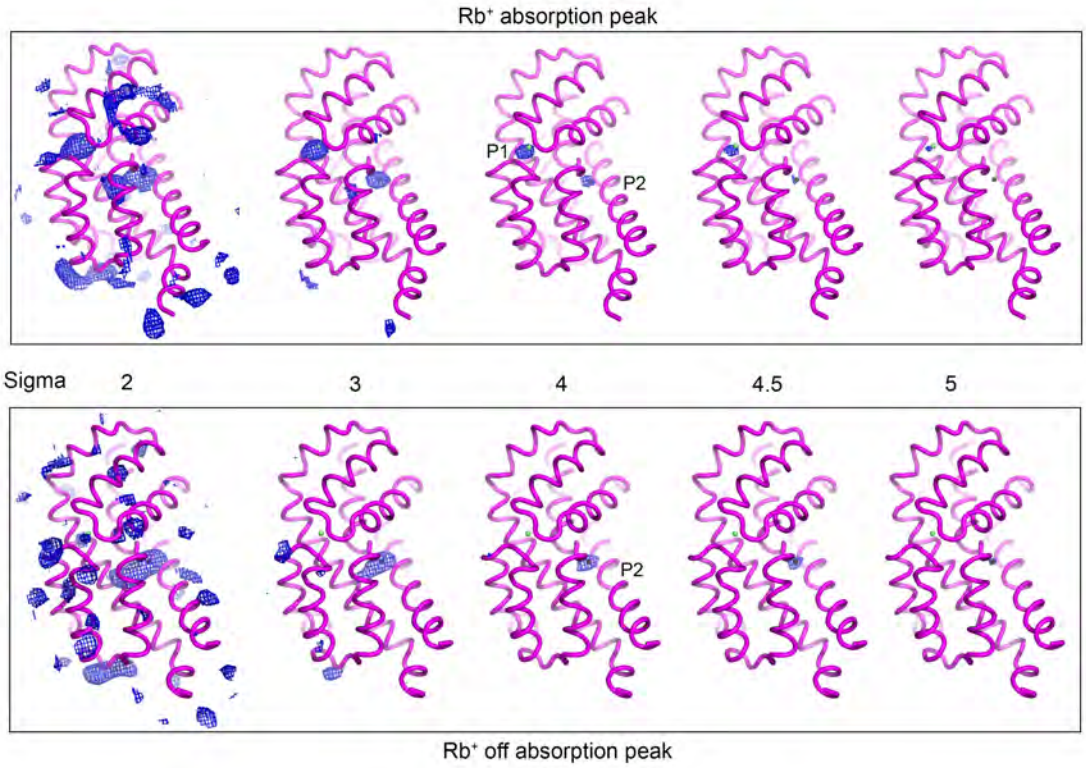

Figure EV2 Anomalous difference maps of Rb^+/Ba^{2+}-bound structure. Comparison of anomalous difference maps of Rb^+/Ba^{2+}-bound $EAAT_{CRYST}$ structure at the Rb^+ absorption maximum (0.815 Å), and that of $EAAT_{CRYST-II}$ off the Rb^+ absorption maximum (0.998 Å). Maps are contoured at increasing sigma levels around the tranD. Rb^+ (green sphere), and Ba^{2+} (black sphere) bound to the transporters are depicted.

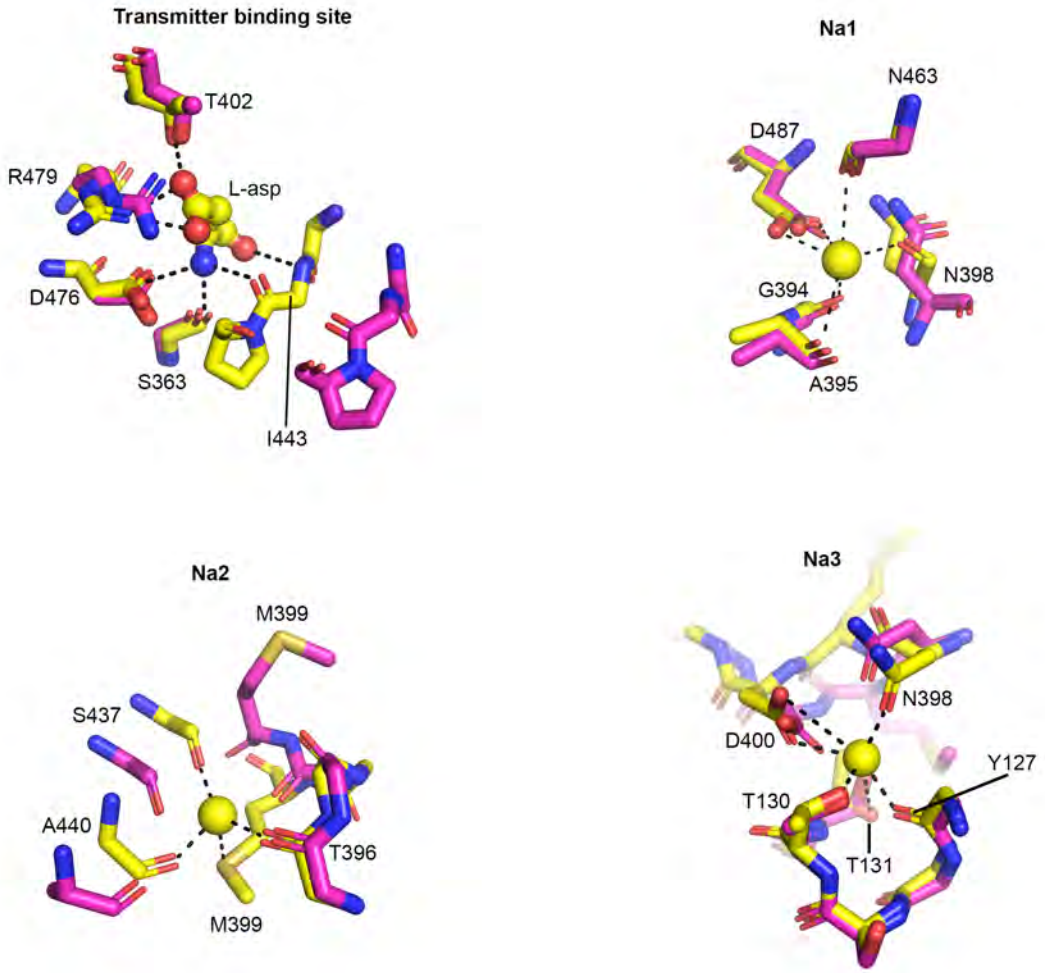

Figure EV3 Transmitter and sodium binding sites in Na^+/transmitter- and Rb^+-bound structures

Conformational re-arrangements around the transmitter and three Na^+ binding sites in Na^+/transmitter- (yellow) and Rb^+-bound (pink) $EAAT_{CRYST}$ structures.

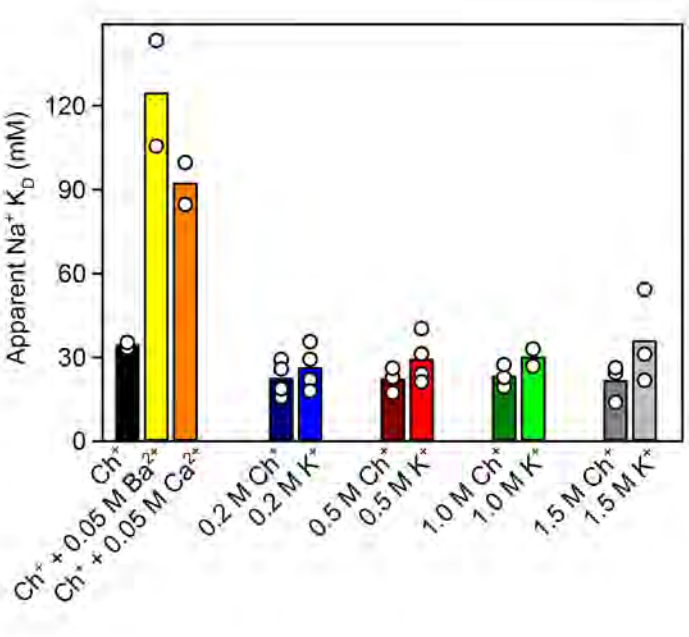

Figure EV4 Na^+ titrations in different ionic conditions

$EAAT1_{CRYST}$ apparent Na^+ K_D significantly increased upon addition of 50 mM Ba^{2+} or Ca^{2+} to a choline (Ch^+)-based cuvette buffer, but were not modified when Ch^+ in the buffer was substituted for K^+ at concentrations up to 1.5 M. Bar plots present average of at least two independent experiments (empty circles).

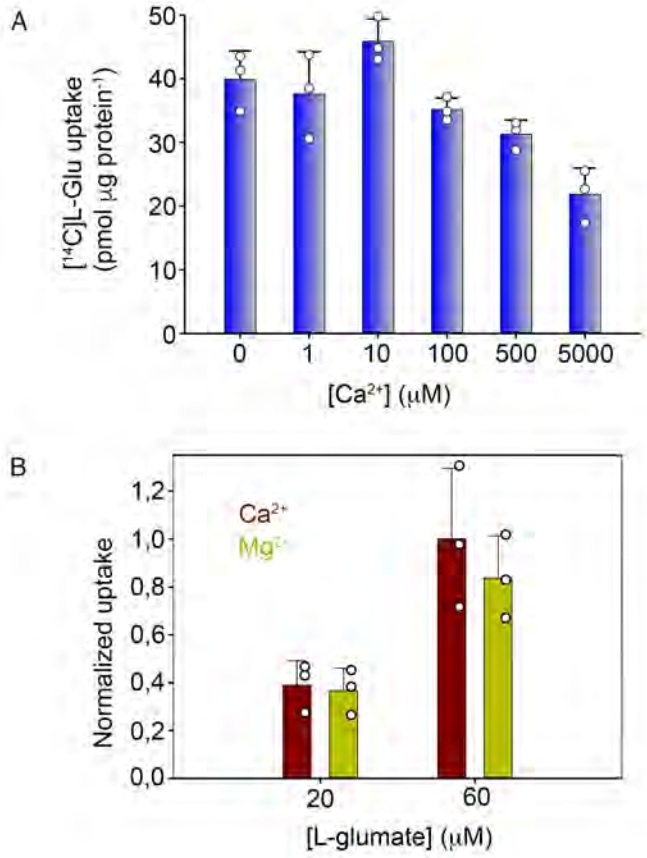

Figure EV5 Ca2+ effect on steady-state transmitter transport

A. Effect of intra-liposomal Ca^{2+} on L-glutamate transport in the presence of opposite gradients of Na^+ and K^+.

B. Effect of 5mM extracellular Ca^{2+} on L-glutamate transport in cells expressing $EAAT1_{CRYST}$. There was not significant change in Na^+-induced L-glutamate uptake upon substitution of extracellular Ca^{2+} for Mg^{2+} , a divalent cation that does not induce changes in Trp fluorescence or compete for Na^+ (not shown).
